According to the advocates of the light rolling stock system, heavy engines are required only because the trains are heavy. Keep down train weight, and engine weight is decreased as a matter of course. This object they propose to effect by the use of combined carriages and engines. Whether this arrangement is or is not the best that can be adopted, we are not about to decide. It illustrates very clearly the principles of the light rolling stock system, and, in so far it answers our purpose at the moment. We shall have something to say to its mechanical fitness for the intended purpose hereafter. In this arrangement the weight of the engine is very small comparatively, and the load it is to haul is also light. It is urged against light engines that they lack adhesion. Quite so; but adhesion is a comparative term after all. That one of the new engines will not possess enough adhesion to haul a 300 ton train is quite true: but it is not wanted to haul 300 ton trains, or even 100 ton trains; and if it can be shown that it possesses adhesion enough to haul the greatest load which it is intended to haul, then it has adhesion enough. Now by making some of the wheels of the vehicle as a whole, not only carry all the engine, but a part of the load as well, it is apparent that the engine must be better off for adhesion, *cæteris paribus*, than any ordinary tender engine—better off, indeed, than any tank engine. There is no room whatever to doubt that the proposed carriage will do what it professes to do, at least so far as adhesion is concerned.

The entire weight of a combined passenger carriage and engine need not exceed sixteen tons, to convey 90 passengers, weighing six and a half tons. There is not at this moment a railway in the kingdom conveying the same number of passengers which does not put in motion a dead weight of 34 tons, or more than double that of the combined carriage. In one case 2.461 tons of dead weight are employed in the conveyance of each ton of passengers; in the other, the dead weight is to the paying load as 5.23 to one. Nor is this all. The sixteen tons of the combined carriage may be, and should be, carried on eight wheels, and no pair of wheels should carry more than five tons. If an ordinary locomotive is used, the smallest weight on at least two pairs of wheels must be double that on the two pairs drawing the combined carriage, for as the load is more than double, the adhesion must be more than double, and the adhesion is as the weight—unless, indeed, the locomotive is to have less adhesion than the combined carriage. And if it is admitted that it can do with less, then the argument that the combined carriage will not have adhesion enough falls to the ground. But it may be shown that the injury done to permanent way will be as great by one pair of heavily loaded wheels as by four or five pairs—that is to say, if in a train 100 wheels are loaded with but two tons each, while the single drivers of the engine are loaded with five tons each, then the road must be strong enough to carry not the light but the heavy load. It follows that rails weighing 45 lb. to the yard would carry the combined engine and carriages as well as 60 lb. or 70 lb. would carry trains worked on the ordinary system. Or that if existing track is retained, it will, if the rails are of good quality, cost little or nothing in repairs, the road being practically indestructible under the assumed conditions of load. It follows, therefore, that the expense of road maintenance may be enormously reduced by the adoption of the combined system. We shall show in a moment how great a saving may be effected in running expenses.

"But," it will be urged, no doubt, "if the light system is so good, why has it not come into use long since?" Now, on this point we are not prepared to speak fully. We believe we may go so far, however, as to say that its non-adoption has resulted from causes which have had nothing to do with questions of mechanical science, and we shall not further refer to them. The best answer that can be brought to all cavilers lies in facts, and we shall, for convenience, first sum up all the objections which, so far as we are aware, have been brought against the combined carriage system, and then proceed to consider them in connection with facts.

1st. Steam carriages must lack adhesion.

2d. They must be slow, because their boilers must be small.

3d. They cannot be competent to deal with exceptional traffic, as, for instance, on market days in country districts.

Now, it so happens that every one of these points was raised and settled long since. It is a great mistake to suppose that we have been theorizing all this while; on the contrary, every statement we have made in favor of the light rolling stock system, and the whole purport of this article, is borne out by the practical results obtained from the actual use of combined carriages and engines years ago.

Some twenty years ago Mr. Gregory had a combined carriage and engine from Mr. W. B. Adams to work the Tiverton branch of the Bristol and Exeter Railway. This steam carriage was christened the Fairfield. The machinery and carriage body were on one frame, 40 ft. over all, hung on six wheels; the two leading wheels, 4 ft. 6 in. in diameter, being the drivers. The wheel base was 28 ft. long, and peculiar provisions were introduced to let the machine get round curves. The cylinders were 8 in. diameter, 12 in. stroke. The boiler, of the ordinary type, was 7 ft. 7 in. long in the barrel, and 2 ft. 6 in. diameter. It contained 115 tubes $1\frac{1}{2}$ in. by 8 ft. The fire-box was 2 ft. 6 in. long by 2 ft. 3 in. wide, by 4 ft. high. The heating surface in the box was 37 ft., in the tubes 325 ft. The carriage carried fifty-eight passengers.

Now let us see how far the performance of this steam carriage justified the objections urged against the system. First as regards want of adhesion. We find that the Tiverton branch was five miles long, and had a gradient of 1 in 86; the fact that this was regularly worked in all weathers, is proof that the adhesion was sufficient. Next, as to speed. The Fairfield ran from Exeter to Bristol, 76 miles, with an extra load behind her weighing ten tons, equal, say, to 140 passengers in all, in three hours 37 minutes. Of this time 58 minutes were spent stopping at twelve stations, leaving her regular pace 28 miles an hour. The maximum speed attained on this trip was 47 miles an hour. So much for speed. Now for capacity. The Fairfield took as much as 31 tons—that is to say, three other carriages loaded, up the Tiverton gradient of 1 in 86, doing the five miles in eleven minutes, or at the rate of 27 miles per hour. This surely demonstrates the practicability of attaching more carriages when necessary, and therefore of rendering steam carriages quite competent to the discharge of abnormal duties. The consumption of fuel on regular work was 8.7 lb. of coke per mile. After working the Tiverton branch for some time the Fairfield was put on the line from Clevedon to Yatton; on this road her regular speed was 24 miles per hour, she ran sixteen trips, or 64 miles per day, and used, in doing so, $397\frac{1}{2}$ gallons of water, and the total cost of running, exclusive of repairs, was but $3\frac{1}{2}$d. per mile.

The results obtained from the Fairfield were eminently satisfactory—satisfactory enough, we think, to justify the favorable opinions we have expressed regarding the system; but we have still more conclusive evidence to urge in its favor. Mr. Samuels designed a carriage built by Mr. Adams, and called the Enfield, which was put to work on the Great Eastern Railway. We are indebted for the following facts relating to the Enfield to a paper read by Mr. Samuels before the Institution of Mechanical Engineers:

The Enfield had 8 in. cylinders and 12 in. stroke; driving wheels 5 ft. diameter; distance between centers, 20 ft.; width of framing, 8 ft. 6 in. The boiler was of the ordinary locomotive construction, 5 ft. long by 2 ft. 6 in. diameter. The fire box was 2 ft. $10\frac{1}{2}$ in. by 2 ft. 6 in. There were 115 tubes of $1\frac{1}{2}$ in. diameter, and 5 ft. 3 in. in length, giving a total of 230 ft. heating surface in the tube. The area of the fire box was 25 ft., giving a total heating surface of 255 ft. The weight of this steam carriage was 15 tons 7 cwt. in working trim. The engine and carriage being combined, it is evident that the weight on the driving wheels was increased by the load carried, and that this weight increased in the same ratio as the load required to be taken. The extreme distance between the centers of the leading and trailing wheels being 20 ft., accounts for the steadiness of this machine; there was, indeed, no perceptible oscillation when traveling at the highest speed, and this verifies the observation, "that the steadiness of an engine depends not on the position of the driving wheel, but upon the length of the rectangle covered by the wheels." This engine, at the same time, daily traversed curves of five or six chains radius. The Enfield steam carriage was originally intended to convey 84 passengers, but as it was found that when she was put on as an express train the passengers increased in number, a North Woolwich carriage was attached capable of conveying 116 passengers, and also a guard's brake-van, making provision altogether for 150 passengers, which was her regular train, taken at a speed of 37 miles per hour.

The following return shows the miles run and coke consumed by this engine during the seven and a half months' regular working, from January 29th to Sept. 9th, 1849:

Total miles run..........................	14,021
Hours, running time	705
Hours, standing time....................	1,457
Total hours in steam	2,162
Cwt. of coke consumed in running	743
Cwt. of coke consumed in standing	408
Cwt. of coke consumed in getting up steam,	286
Total cwt. of coke consumed.............	1,437
Pounds per mile ave. consumption of coke,	11.48

The Enfield was in steam fifteen hours per day, the fire being lighted about six in the morning and drawn at ten o'clock at night. But of these fifteen hours it appears, by the return, that she was engaged running only five hours, the remaining ten being employed standing in the siding. It was found by experiment that the quantity of coke consumed standing was 32 lb. per hour; and after deducting this and the quantity consumed getting up steam, it will appear that the actual consumption of coke running was under six pounds per mile. It must also be particularly borne in mind that this consumption of coke included the total goods and coal traffic on the branch, amounting to 1,410 tons, viz., 169 tons of goods and 1,241 tons of coal. The Enfield steam carriage worked the 10 A. M. passenger train from London to Ely, on 14th June, 1849, a distance of 72 miles, taking behind her three of the ordinary carriages and two horse-boxes; she arrived at Ely eight minutes before time, and the total consumption of fuel, including the getting up steam, was found to be 8¾ lb. per mile. The tubes of the boiler were only 5 ft. 3 in. in length, and the economy of fuel is consequently scarcely at the maximum. Mr. Gregory expressed, in the paper in question, as the result of his experience, the conviction that, for express purposes, and for the larger portion of the branch traffic on railways, the light steam carriage is the best adapted and most economical machine, both as to first cost, compared with the work done, and in working expenses. The repairs of the permanent way were also very much reduced, as may be easily imagined. On the Eastern Counties Railway, in 1849, an engine and tender of, say, 30 tons, a brake-van, a first-class carriage, and three third-class carriages, conveying 120 passengers, made a total weight of 59 tons, and the consumption of coke was, on the average, 34 lb. per mile. A steam carriage weighing only seventeen tons will transport the same number of passengers at from 7 lb. to 8 lb. per mile when the best proportions are attained.

It is unnecessary, we think, to prolong this article by adding further arguments in favor of the light rolling stock system. We shall, in another impression, consider the nature of the mechanical problems to be solved by the designers of steam railway carriages, and the best methods of solution.

STEEL HEADED RAILS.

In 1866 Messrs. John A. Griswold & Co., of Troy, sent 500 tons of steel headed rails, in lots of 10 to 100 tons, to some dozen different railway companies. The steel surface was about ⅝ in. thick when finished; the rail was a pear-headed 56 lb. pattern, the stem being, as it proved, too light for very heavy engines. Under a yielding iron head, the web had proved strong enough. Under the very heavy engines of the New York Central and Michigan Southern, some of these rails failed in the stem, but the heads rarely became loosened. The wear was, however, in the worst cases, very much better than of iron, and the greater number of the rails are still in use on these lines, although placed where they endure constant switching and unusual wear. On some lines, where the machinery is somewhat lighter, these rails are all in excellent condition. Some on the Hudson River road, between Albany and Troy, show hardly any deterioration. The report of the Eastern Railway (Mass.), for 1868, says of them: "We have had 25 tons of iron rails with steel heads, in use as an experiment, in our main track for upwards of two years, and so far with the most satisfactory results." The Superintendent of the Boston and Providence Railroad, says of some of the same lot of rails: "I take pleasure in saying that a lot of steel-headed rails, furnished by John A. Griswold & Co., in 1866, are wearing equal to the best English (steel) rails; indeed there is no difference. These rails are laid on one of the most exposed places on this road." On the whole, this steel-headed rail has proved itself equal to about three of the best iron rails.

The heads of these rails were made from some of the first Bessemer steel produced at Troy, and were rolled into slabs deeply grooved on the under side, where they were to be joined to the iron pile. The weld, or the weld and the dovetail together, made a much more perfect union between the head and the rest of the rail, than is usually made in iron. The three years practical test, and numerous tests by the trip-hammer, have shown the union to be sufficient, and nearly uniform for the whole lot. With a heavy, strong iron body, such steel-headed rails should wear, for some years, as well as all steel, but of course they would not be as stiff, and when the head was worn very thin, it would doubtless come off. The practicability of making a good steel-headed rail, by this method, is certainly proved.

Another kind of steel-headed rail is being produced by Mr. Coxe, at the Reading Railway Company's mill. The cut, Fig. 1, shows the method of laying up the pile (9 in.), the shaded parts being separate small bars of low cast steel, made at the William Butcher Steel Works, Philadelphia. Fig. 2 (full size) shows the steel as it appears in the finished head.

Fig. 1.

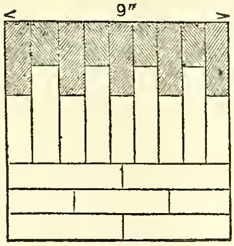

Fig. 2.

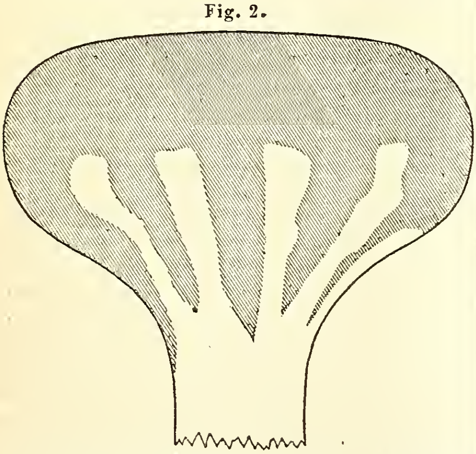

The welding appears very good, although the head cannot be as homogeneous as a solid slab. With some of the piles, borax, fireclay, and sand were used as flux; with others, the Hindermeyer flux, which was quite satisfactory. Some 20 tons of these rails have been laid in one of the hardest places in the Reading track, which will soon determine their value.

THE HISTORY OF GUN-COTTON.

THE EARLY MANUFACTURE—ITS DANGER AND ABANDONMENT—LENK'S IMPROVEMENTS—NEW DIFFICULTIES—THE MANUFACTURE IN ENGLAND—ABEL'S IMPROVEMENTS—PRESENT PROCESS AND RESULTS.

Compiled from the London "Times."

In the year 1846 Professor Schönbein, of Basle, announced that he had discovered a substance possessing all the useful qualities of gunpower without the defects. Gunpowder is dirty, rather dangerous to manufacture, and leaves behind it when exploded both a considerable quantity of solid matter, fouling the piece within which it has been consumed, and volumes of stifling smoke. The invention made its way into popularity with great rapidity, for what can be more desirable than an explosive material of great strength in the form of a soft, clean substance that gives no smoke in its combustion, and leaves no traces behind? The idea of gun-cotton was not entirely new. Braconnet in 1833, and Pelouze in 1838, had produced a material called xyloidine, very similar in its nature to gun-cotton. Pelouze had even proposed its employment for artillery purposes, but the subject had never attracted much attention till Schönbein exhibited the substance itself to the British Association at Southampton in 1846 In the same year he proposed it for trial in France, Prussia and Austria. A general enthusiasm arose; and, while Messrs. Hall, of Faversham, began to manufacture it in England, foreign governments seized upon the idea, and began to carry it vigorously forward.

But if its popularity arose and spread rapidly, so did the reaction against it. Terrible explosions occurred in factories and magazines—not in one country, but in all. In England three men who were making gun-cotton rockets were killed on the 24th of June, 1847; and on the 14th of July such a fearful explosion happened at Messrs. Hall's factory that gun-cotton became as much dreaded as it had been welcomed before. The two buildings in which the manufacture was in progress had walls eighteen feet thick, and were separated by a huge mound of earth forty feet high. Yet the echoes of the first frightful roar had not been given back before the second building blew up. Late discoveries seem to throw some light upon this phenomenon, which has often been noted as occurring even in gunpowder explosions. A distance of two or three hundred yards has been found insufficient to break this terrible sympathy—for sympathy it probably is. At Messrs. Hall's works twenty-one persons were instantly killed, and sixteen suffering wretches lay mangled or burnt upon the ground. The manufacturers would have no more to do with so deadly a material. No one could tell how either of the explosions had occurred. A dread mystery hung over the event, and Messrs. Hall set men to dig a deep pit, into which they threw all the gun-cotton they had made, right thankful to see it interred alive. And alive it was still. Sixteen years afterwards some of it was dug up for experiment. The rains had filtered through it. The earth, greatest of all chemists, had worked what it could upon the soft white mass, but its nature remained the same, and its force was but little abated. It is not necessary to say that gunpowder would, under such conditions, have melted into a black paste, and, gradually parting with its saltpeter, have become perfectly innocuous. The French government and the German Confederation were almost equally unfortunate ; and the worst feature was that no amount of care seemed sufficient to preserve gun-cotton from ignition. The ugly phrase "spontaneous combustion" was whispered about, and every report was unfavorable to the new explosive.

Among the officers composing the committee assembled from the different armies of the German Federation was a certain Austrian captain of artillery, called the Baron von Lenk. Agreeing with his coadjutors that gun-cotton, in its actual state, was not suitable for military purposes, he yet believed that it could be made so. Encouraged by Count Degenfeld, he prosecuted his experiments, and found out how to render it safer. He also tried to control its action; for one of the great faults of the old gun-cotton was its excessive rapidity of inflammation, and consequently destructive effect upon the gun in which it was fired. The safety was gained by a more complete conversion of the original material into gun-cotton, and its subsequent purification from all traces of uncombined acid, as far as was possible, in his method of manufacture. The regulation of the action was obtained, so far as it was obtained at all, by using skeins of twisted cotton in the first instance, and then winding them round wood, twisting them into ropes, or compressing them into comparatively solid masses. Some success was attained, and the Austrian government again took up the question. When an army of observation was placed in Galicia during the Crimean war, four batteries of eight guns each were provided with gun-cotton charges. There was no opportunity of trying them in battle ; but experiments showed that the new material was uncertain in its action and destructive to the guns. Some of the charges even ignited during the process of loading. Artillery officers almost unanimously rejected gun-cotton; and it would have been forgotten, but that none of its objectionable properties seemed to hinder its employment for mining purposes, while the suddenness of its effects rendered it peculiarly well adapted for blasting rocks and submarine explosions. So the engineers received it as it fell from the hands of the artillery, and have never since entirely rejected it. They had stores of it in Venice and the Quadrilateral during the war of 1859 ; and even the artillery, being in want of something that could be called new to oppose to the French rifled guns, prepared gun-cotton batteries in Vienna, which were, characteristically, just ready for service when peace was concluded at Villafranca. Scarcely had a few rifled guns been made on the French system, when it was found that they would not do. Count Degenfeld was appointed Minister of War, and again brought gun-cotton forward for artillery. An ingenious system of rifling was devised. and tried with gun-cotton. The results were good enough to warrant the Minister in ordering thirty batteries (240 guns) to be prepared and equipped in the same manner. Some of the European nations which had dropped the subject since 1847, England being one of them, sent officers to study the details, and learn Lenk's system of making gun-cotton. But just then came reports of unlooked-for burstings of shells and mining charges in Italy or at Vienna, and, finally, the blowing up of a magazine at Simmering, near Vienna, where gunpowder and gun-cotton were stored together. The old mystery hung over the occurrence. No fire had been near the place, as well as could be learnt. It was enough. The Austrian artillery had burnt their fingers too often; they would have no more of this soft, white, treacherous substance, which promised so fairly only to betray. It fell completely out of favor, and nothing has been done with it since in Austria, except for mining purposes and torpedoes.

But the British Association had taken up the matter again in 1862, under the advice of General Sabine, R. A., President of the Royal Society. A committee was appointed, their report was read in 1863, and at last the English government appointed a committee to investigate the whole subject. According to British usage, they began at the beginning, and worked doggedly on through all previous experiments, leaving nothing unproved. They had just cleared the subject from most of the fog that obscured it, and the light was beginning to shine pretty clearly, when, again according to British usage, the committee was suddenly dissolved. Fortunately, Mr. Abel, F. R. S., chemist to the War Department, had become a convert to the possibility of eventually finding a substitute for gunpowder, either in gun-cotton or some analogous substance. His researches have already carried the subject far beyond any point previously attained, and the progress made has been so considerable that gun-cotton may now be considered as quite fit for sporting purposes, and on the way to become so for rifled small arms, perhaps even for field artillery. It appeared as if chemists could in nowise satisfy themselves as to the value of the material until they had put a hard name to it. As long as it was only gun-cotton it made no progress. It languished even as pyroxylin, but has moved steadily forward ever since it became tri-nitro-cellulose, a rich name and comfortable to the mind.

It was, therefore, not to see gun-cotton made and tried, but to witness the manufacture and investigate the properties of tri-nitro-cellulose that a party of scientific gentlemen and military officers, French and English, recently went down to Stowmarket. Mr. Abel's improvements have been adopted by Messrs. Prentice, and at their works alone can now be studied the latest forms which this material has put on.* The Austrian manufacture stopped at the point where the cotton was supplied in the form of skeins, which were dipped in a mixture of nitric and sulphuric acid, then placed in jars to soak thoroughly, then half dried in a centrifugal apparatus, and afterwards washed thoroughly and long by hand and in running streams until no free acid could be detected. For small arms cartridges a hollow plaited rope was then made of it, cut into lengths, and arranged round little wooden spindles, the ends of which penetrated the bases of their bullets and held fast there. When first Messrs. Prentice commenced their manufacture they were under the advice of Baron von Lenk, and followed the Austrian method exactly. Soon they found the rope plait was inconveniently long. They tried a solid pope, but it inflamed too suddenly and strained the gun. Then they tried a solid rope of mixed gun-cotton and common cotton. This was not so dangerous, but its action was not always the same. They tried also what may be called gun blotting-paper, and rolled it up into cylinders for cartridges, but they have now exclusively adopted Mr. Abel's newer methods, which have the two advantages of rendering the gun-cotton perfectly safe and almost perfectly manageable—safe because the great thing to be avoided is a mass of cotton, either imperfectly converted or containing free acid. Cotton, like hair in its ordinary state, is made up of a vast number of small tubes, which all have the power of taking in liquid by capillary attraction, and retaining it in spite of all washing. If there is any free acid in the gun-cotton it has many opportunities for combining chemically with other substances, and so setting up heat which accumulates, and may at last fire a portion of the mass. Mr. Abel obviates this by tearing the cotton into fragments, making it, in fact, into pulp. The process of making gun-cotton at Stowmarket is thus carried on :—

Rough waste cotton. no matter how short the fiber, is cleaned thoroughly, dried, and dipped into a mixture of three parts sulphuric acid to one of nitric. If the acids were weak, the cotton would dissolve. With the strong acids used a combination of the nitric acid and cotton ensues, while the sulphuric acid takes up the water left behind by the nitric acid and so keeps the latter always strong. There is a row of small tanks fed with acids through pipes from a reservoir. Into each of the tanks one pound of cotton is dipped, care being taken to immerse it all completely. It is then taken out and laid upon a grating over the tank to drain, and thoroughly squeezed by iron paddles. Twenty minutes suffice for this operation. The converted cotton now goes into jars, which stand in water to keep them cool, for much heat is

* The Messrs. Prentice commenced the manufacture of gun-cotton under Baron von Lenk's patents in 1863. We had an opportunity to witness the first experiments made by them, which, together with many other experiments and facts of interest concerning gun-cotton, are very fully considered in the appendix to "Ordnance and Armor."—*Ed. V. N's. Magazine.*

developed in the combination. After soaking here for many hours, the cotton is placed in a revolving drum with small holes in its exterior. It whirls rapidly round, and discharges most of the spare acid by its centrifugal force. Then comes a very important process—the washing. First the cotton is thrown into a fall of water, and a man watches to prevent any of it escaping instantaneous immersion, otherwise the acid and the water would set up an action strong enough to burn some of the cotton, or, at least damage it. After thorough washing in a tank under the waterfall the material is placed in a vat to steep in water for twenty-four hours; then it goes to a second and a third, and so on for a week. By this time no acid is perceptible. The cotton is then placed in a mill like that used in paper-making. The water used to make the pulp is slightly alkaline, in order to take up the last traces of acid. The next operation is drying again in a centrifugal machine. There has now been produced a gun-cotton pulp, which has only to be pressed into the shapes most convenient for its intended purpose. The most common forms are those intended for fowling-pieces and blasting. Another invention has lately been introduced to render the cartridges impervious to damp. There are 30 grains of cotton to a gun of No. 12 bore. One grain of india-rubber dissolved in 30 grains of spirit is then used to saturate the pressed gun-cotton. After drying, the spirit evaporates, and the caouchouc remains throughout the mass, completely preserving every particle from damp, though gun-cotton does not deteriorate by damp so long as it be dried again before firing. Almost everything that is made of gun-cotton has a hole through it to facilitate combustion. The pulp is first pressed in a very wet state, and then pressed yet smaller before drying. It is finally dried, and put in boxes for use. The pulp and various shapes into which it is pressed are Mr. Abel's inventions.

Such is the manufacture of gun-cotton. Some of its properties are most curious, and really deserve to be called sympathetic. For instance—take a loosely-twisted thread of gun-cotton, and lay it on a flat table, carefully drawing out a few filaments at one end, so as to form a point. Light a small piece of wood, a match if you will, but blow it out as soon as the wood is well inflamed. Approach the spark that remains delicately to the extended filaments. They meet it and begin to burn. But how? Very far from explosively. The whole thread smoulders away like touch-paper so long as no wind blows upon it. But blow the flame the least towards the rest of the thread, or even bring a flat surface close to it so as to push the heated gas for one moment back upon the thread, and the whole goes off in one flash in the ordinary way. Light it with the flame of a match, the whole flashes off at once. Go one step farther, and ignite it by a little detonating arrangement, the gun-cotton sympathizes again and actually detonates. Since this curious property was discovered, it has been found to apply to gunpowder in a more limited form; and here have we not the long-sought clue to the sympathetic explosion of one magazine after another even when at considerable distances apart? Neither a layer of air, nor water, nor even plaster of Paris, will save gun-cotton from detonating if there be an explosion of the same character near it. Here is a strange physical property which will be of the utmost value in mining. It is the sudden and violent effect of nitro-glycerine without its character of treachery to its friends. The miner has in his charge of gun-cotton two perfectly different physical forces stored up. He can call either of them into life at his will. Let him light his piece of prepared rope with any ordinary flame, even the explosion of gunpowder—the gun-cotton will give just such a rending strain as gunpowder gives—rather more rapid, but of the same nature. Place a small detonating tube inside your rope or leaning against it, ignite this, and the gun-cotton will explode with the same rapid, active, intensely local explosion, shattering to atoms all that is within reach. The smouldering form of burning is as yet too delicate to be made practical use of. The mildly explosive form is adapted for guns, the rapid shattering for any purpose where great local effect is to be produced, such as shattering rocks into small pieces, charges for shells, blowing down palisades, and generally breaking anything into pieces.

Illustrations of the two latter forms of explosion were given abundantly recently (Jan. 22). After seeing the processes of manufacture, the visitors went to the shooting-ground and not only saw some practice, but ascertained personally the comparative effect of gunpowder and gun-cotton in a fowling-piece with small shot. The penetrative effect was about equal. The gun-cotton cartridges threw closer, and in a very marked degree. It mattered not who took the gun in hand, the average difference was always about the same. The recoil of the gun was much less with gun-cotton than with powder. This is very well known, but we are disposed to venture a different reason for it from the one commonly given. It is usually said that the gas produced has to move solid grains of powder as well as shot. The difference must be very trifling, and cannot possibly account for the extraordinary want of kick in guns fired with gun-cotton cartridges. We believe that the action of the gun-cotton is more local because more rapid, and expands itself in creating motion in the particles near at hand when the explosion occurs, rather than in moving the whole mass of the gun. This theory seems to be confirmed by the fact that as gun-cotton is more diluted by inexplosive cotton it gives more recoil. If we are correct in this supposition, it is clear that the gun-cotton strains the gun more, but fowling-pieces have generally a large margin of strength, and the charge of shot moves much more readily than a bullet in a rifle. This supposition may also account for the closer throwing of shot from the gun, for the greatest pressure of the gas occurs while the shot is yet far from the muzzle; hence less tendency to separate at the momont of leaving the gun.

As the first experiment against palisades, a disc of gun-cotton, weighing about 1 lb. 1 oz., was placed on the stump of a tree lately cut down and ignited by an ordinary piece of miners' fuse. At the instant of ignition it was enveloped in flame and sailed merrily about for the two or three seconds required for its combustion. The gas produced lifted it up and caused it to move. Then about half the quantity was placed on the same spot and ignited by a small detonating tube. A sharpe, sudden report was heard, and the stump was found on inspection to be partly penetrated just where the charge had lain, while the twigs of the hedge close by suffered severely. On seeking for a new illustration, a large tree-root was seen which had been torn out of the ground, and offered among its gnarled and bossy structure a favorable position to deposit a charge. One of the discs about 1 lb. 1 oz. was accordingly placed at the mouth of a small cave that seemed inviting. The gun-cotton was not buried in the mass, but only laid as it were on a shelf perfectly open to the air. The gentlemen present retired to what they considered a safe distance, about 50 yards. There seemed to be some doubt about the effect. Is it possible that so small a quantity of gun-cotton could rend such a mass even if buried in it? Surely not when it is only laid on the floor of an opening. The moment of explosion is anxiously awaited. A man lights the fuse and runs for his life. There is a little smoke. Is the cotton burning as the first sample did? Wait a little yet. The tube has not given its sharp cracking sound. One moment more, and then a report and a rush through the air of masses of wood. Overhead, right, left, in front, everywhere. Soldiers who have known what it is to be under shell fire ducked to dodge a big lump of knotted wood that sprang 64 yards from its parent root, just clearing the heads of the party. It was only for a moment, and then everybody ran to see what had been done. The whole great root had simply been shattered to pieces. The next experiment was on a row of palisades composed of three trunks, some of them eighteen inches in diameter, and all sunk four feet into the ground. A long tree-trunk lay touching the foot of the palisade, and upon this 5 lbs. of gun-cotton was laid. Wires communicating with a magnetic apparatus were affixed to a detonating tube, which was placed in contact with one of the discs of gun-cotton. The time of suspense was short, and then the explosion was heard. One mass of wood only was seen to plunge away from the palisade; it was the recumbent trunk upon which the cotton had been laid. The palisades themselves were standing, though a good deal damaged. No practicable breach.

But there still remained a long space of palisading yet untouched, and here, instead of 5 lbs., 15 lbs. were laid, partly built upon each other. The excitement began to increase. It was the old story of the targets and the guns, and now several people might have been found to back the palisades. Fuse and wires were placed. Everybody retired to a safe distance. At last came the sharp, powerful crash, so unlike the dull roar of gunpowder, and this time there could be no mistake about the effect. Huge logs were seen performing somersaults at greater or less distances from the explosion, while smaller pieces, some about a couple of feet square, bounded like rabbits over the field. On reaching the target the effect appeared to have been tremendous. In some places a tree-trunk had been cut in half almost as if with a rough saw, only not so straight.

In others the solid wood was mangled so that it could be pulled to pieces by the hand. Three logs had been cut down or smashed, and it was clear that no stockade or New Zealand pah could withstand such deadly effects for an instant.

And all this had been done by only 15 lbs. of the cotton. Three times the quantity made up into a cylinder could be carried with ease by a man at a run, who might also drag the ends of the two wires as they unwound from a reel kept in a position of safety. No fire need be seen, for there is no match to light. Surely plenty of volunteers could be found to perform such work at night, and so restore the superiority of civilized man over savages! It had been contemplated to tie a ring of gun-cotton round a living tree, and see if it could not be cut down, but there was not time enough. The experiments were over for the day, and the visitors returned to London satisfied that they had seen a most marvellous phenomenon, and one which is only a first step to a whole array of novelties in the arts of war and of peace.

FRENCH NAVAL ENGINES.

Notes on the comparative experiments on three cylinder Engines in the Imperial Marine, by M. le Vice-Admiral Labrousse.

Translated for "Van Nostrand's Magazine" from "Le Génie Civil."

(EDITOR'S NOTICE).

The readers of "Annales du Génie Civil" will recall that one of the most important questions connected with the application of steam to war vessels, has been already discussed in our magazine. We refer to the determination of the relative merits of two systems, simultaneously employed in our navy. The one, derived from the Woolf system, (but which does not make use of very high pressures nor of great expansions,) introduces the steam directly into a central cylinder, during $\frac{85}{100}$ of the stroke, and then allows it to expand into two other cylinders attached to the first and of equal capacity. The other system, which employs steam at a moderate pressure, gives it access to each of the three cylinders through $\frac{30}{100}$ to $\frac{65}{100}$ of the stroke, according to circumstances.

Vice-Admiral Labrousse, as the result of prior experiments and the most exhaustive theoretical considerations, endeavored in the article alluded to, to show that this latter system has incontestable advantages over the former, both in a mechanical point of view, and in its military relation, and concluded by insisting upon the immediate abandonment of the objectionable system, and the transformation of its machinery—a matter of no great difficulty. The arguments of the honorable admiral, whose qualifications in all that relates to steam engineering nobody will venture to question, have not, it would seem, been regarded by the directing administration as sufficiently conclusive to warrant the instant adoption of so sweeping a decision; but it has seemed advisable to seek in new experiments a more decided and authoritative comparison and more accurate results upon so grave a question. During the past summer many instructive experiments were undertaken by the iron-clad division of the navy; the programme, it is but justice to say, having been arranged by M. Puys de Lôme, the author of these same engines which are charged with inferiority. In this case, as in all others, to the party on trial belongs the right of the last word in his defense, until the investigation is completed, and the judges are ready to render a decision. It certainly seems that the time for a decision has fully come, and any further postponement of the issue will look like favoritism, and can only, in the opinion of the admiral, aggravate a situation already most deplorable, nay even fatal, and upon which they cannot, in any other way, shed one ray of light. With a view to bringing home to learned and impartial men his own convictions in this matter, the honorable admiral submits to their judgment all the steps of his investigation, the results of which supremely affect the interests and honor of France, relating as they do to one of the capital elements of her military power. If we were to express merely our own opinion, we should say that our conviction, already prepared by the previous paper of M. Labrousse, is now complete; for it seems impossible to oppose a single valid argument to inferences so clear and convincing. But it is to the enlightened public, to whose judgment the admiral makes his solemn appeal, that the right belongs of deciding between the two opinions before it on this grave question—COMITÈ DE REDACTION.

The armored frigates *Savoie*, *Gauloise* and *Guyenne*, which form a part of the Oceanic naval division, were subjected, a while ago, to some comparative experiments, relative to power and consumption. The *Savoie* has an engine with three equal cylinders, with direct admission into one of them; the *Gauloise* has also three equal cylinders, but with direct admission into all of them; the *Guyenne* is furnished with the ordinary two cylinder engine. The experiments, conducted according to a carefully elaborated programme, have been made with the utmost care. "Nothing whatever," says the report of the commission presided over by Rear-Admiral d' Hornoy, "has occurred to interrupt their course, or to affect, in the smallest degree, their validity." We may therefore consider the results as having all the correctness which is consistent with the official programme. In a former paper, containing an examination of the three cylinder engines, we had arrived at some summary conclusions, founded upon various theoretical considerations, which arose from an exhaustive discussion of the experiments before us. We put them in the following form:

If we compare the new engines of the *Savoie* type with the three independent cylinders of the *Gauloise* type, we must conclude from the foregoing discussion that the latter are superior in every respect.

1. They are on the same footing with respect to consumption of fuel, and yet the latter have attained, with a boiler pressure less than 59 centimetres [of mercury], a power in excess of 4,000 horses.

2. They offer better security for attaining a great number of revolutions, because their method of coupling is more regular [equiangular], because the maximum pressure upon the journals is 50 per cent less, and because injurious effects of heat are less to be apprehended.

3. The static equilibrium of those parts subjected to alternating motion, is more exact—a result of the more regular manner in which the cranks are attached to the shaft.

4. To attain a normal power of 4,000 horses, we can in the engines of the *Gauloise* type, reduce the working velocity adopted for those of the *Friedland* or *Savoie*, either by increasing the pressure (without reaching even 133 centimetres), or by increasing the admission; while in the *Friedland* or *Savoie* type, this power cannot be attained except by exceeding the normal pressure of 133 centimetres, and increasing the working velocity, which is already too high.

5. Finally, as the normal admission in an engine of the Gauloise type, is only $\frac{4}{10}$, when the boilers are deteriorated, we can, without diminishing the power, employ a larger admission, and thus work at a lower pressure, which is impossible with the new engines, in which the admission is already $\frac{85}{100}$.

The experiments with the armored vessels of the Oceanic division, have confirmed these various assertions in the most complete manner, and all the more conclusively because they were conducted upon a programme laid down by the very author of the *Savoie* type of engine. We shall set out these facts in a manner that ought not to leave any doubt in the mind of any reader, however prejudiced in favor of the latter system.

Meantime we may venture the remark, that our object is only to establish an abstract and general comparison between ordinary engines and established machinery after the Woolf system, (properly speaking,) with high pressures, which involve the use of surface condensers when sea-water is the only available source of supply. This will give rise to a question which we shall probably have occasion to touch upon further on, when we come to discuss the military requirements of a vessel. Our present task is less complex. In a word, it amounts to this:

The French fleet contains, either in service or building, nine three-cylinder engines of a thousand nominal horse-power; two with independent cylinders, and seven with direct admission into only one cylinder, according to a system derived from the Woolf principle. In all these engines the boilers are fed with sea-water. The pressure in the boilers should therefore be limited, in the seven engines of the second type, to 133 centimetres—a maximum, beyond which the author of these engines himself admits that deposits of salt cannot be avoided. What we urge is the transformation of these seven engines into engines with direct and independent admission into the three cylinders, for the sake of advantages of every kind, mechanical and military, which undeniably appertain to the latter class. The conversion can be effected with little difficulty, and without affecting materially the internal arrangements of the vessels, and we have already seen by the analysis and discussion of the experiments made with the armored division of the north, that delay in this matter is no longer tolerable. But we proceed to our demonstration.

1. *Experiments proving à fortiori, our first conclusion; greater power with less boiler pressure and equal consumption of fuel.*

TABLE I.

NAME.	Pressure, Centimetres.	Power, H. P.
Savoie	115.8	2,565
Gauloise	60.	3,157
Difference	55.8	592

These figures show at once in favor of the Gauloise an actual power one-fourth greater with about half the pressure.

The consumption of coal, in the determination of which no possible means were neglected which might ensure perfect exactness, are compared in the following:

TABLE II.

Relative consumption per hour and per horse-power of 75 kilogrammetres.

NAME OF VESSEL.	1 BOILER. Consumption.	1 BOILER. Saturation.	2 BOILERS. Consumption.	2 BOILERS. Saturation.	4 BOILERS. Consumption.	4 BOILERS. Saturation.	6 BOILERS. Consumption.	6 BOILERS. Saturation.	8 BOILERS. Consumption.	8 BOILERS. Saturation.

	K.		K.		K.		K.		K.	
Savoie...............	1.929	3°	1.428	3°	1.433	3°	1.400	3°	1.460	3°
Gauloise	*1.920	3°	*1.579	3°	*1.432	3°	1.365	3°	1.331	3°
Difference	+0.009	....	—0.151	....	+0.001	....	+0.035	....	+0.129	....

The report of the commission gives, for the consumption reduced to three degrees of saturation, the figures in place of

1,876	1,605	1,463
1,920	1,579	1,432

which are given respectively in table III, and which are marked by an asterisk. It is apparent that some sensible errors have crept into the reductions made by the commission, and we have worked out the corrections, after having made sure, in comparing the total consumptions, the duration of the experiment, and the horse-power obtained, as set forth in the tables of the commission, that the figures 1,940, 1,603 and 1,454 are correct.

It appears from the foregoing tables that the advantage rests with the Gauloise in every case but one, and that with two boilers—that is, with one-fourth the fires lighted—an exceptional case, which we have never seen in actual service.

With respect to the power developed, it was during the trials of June 27th, 1868, greater by about 600 horse-power (or one-fourth greater) on the *Gauloise* than on the *Savoie;* while the pressure, which was 115.8 centimetres on the *Savoie*, did not exceed 69 centimetres on the *Gauloise*. The first of our conclusions is thus confirmed, even beyond our expectations; but even though the commission had reversed the results—that is to say, even though the *Savoie* was made to show in the report of consumptions an advantage which properly belonged to the *Gauloise*, we none the less continued to urge the conversion of engines of the *Savoie* type into the *Gauloise* type, taking our stand upon the following considerations, which we explained in our first paper upon these engines.

"An economy reaching even 20 per cent (M. Dupuys de Lôme's figures in his note to the Academy) is not sufficient to compensate for the defects of his engine. The defects are all the more serious because their principles may pass unobserved in time of peace; for the occasions on which the machinery of our war vessels will be called upon to develop their utmost power, will be rare and of brief duration; but in war, and in the hours of supreme emergency, the speed, which, in M. Dupuy de Lôme's engines requires the highest pressures and a perilous velocity of the piston, will be often demanded and will be had whatever the cost. Their dangerous character will then be fully realized."

We proceed to examine our second conclusion. The more perfect equality of the couple of rotation in the *Gauloise* engine, appears from the fact reported by the commission, that the *regular* motion may be reduced down to nine revolutions [per minute], while in the *Savoie* it ceases to be regular at twelve turns [per minute]. If the power may be regarded, within the limits compared, as proportional to the cubes of the number of turns, then the minimum forces consistent with the regular performances of the two will be in the ratio of 729 to 1,728, or as 1 to 237. The first part of our second conclusion then is abundantly warranted by the experiments of the Ocean division.

With respect to the second part of that conclusion, viz: maximum pressures upon the journals; it is well sustained by results. We have elsewhere demonstrated that, supposing the mean pressures to be equalized in the cylinders of the *Savoie*, the interposition of inertia would involve a great increase of relative pressures upon the journals. This increment of pressure will be greatly augmented in the present case, because the mean tensions of the steam are widely different in the different cylinders. Finally, we asserted that injuries resulting from the high temperature of the steam are less to be feared in the *Gauloise*. We infer this from the fact that about the same powers are obtained on the *Gauloise* (3,157 horses), with 60 cm. of boiler pressure, representing 117° C., and on the *Savoie* (3,215 horses) with 141.8 cm. of pressure, representing 134° C.

Our third conclusion as to the static equilibrium of moving parts was evidently correct *à priori*, so far as it applies to the *Friedland* type of engine, of which the cranks are attached at 90 and 135 degrees. On the *Savoie*, where the cranks are attached at 120 degrees, (the same as the *Gauloise*), the inferiority of the static equilibrium shown in the experiments, results from the difference in the tension of the steam in the cylinders, which the attachment at 90 and 135 degrees is expressly intended to obviate, but is more injurious than useful in the present case.

Our fourth conclusion is with reference to the means of obtaining great power with low pressures in the *Gauloise* type. This would be evident enough *à priori*. But to show that it is sustained experimentally, it may suffice to quote the figures. The *Gauloise* has developed 3,544 horse-power with $\frac{4}{10}$ admission and 88.8 cm. of pressure, while the *Savoie* has developed only 3,215 with 141.8 cm. Comment is superfluous.

There remains the fifth conclusion, viz: sustained power in spite of deterioration in the boilers. The Gauloise realized (17th of June) 3,157 horses with only 60 cm. pressure, while the Savoie, to realize an equal power (3,215 horses), had to push the pressure to 141.8 cm., and with 105 cm. her power reaches only 2,207 horses; indeed at this moment the boilers of the *Magnanime*, (same engine) though in good condition as yet, are so weakened over the fires, that it is not deemed prudent to exceed 100 cm. of pressure, and the engine is barely capable of developing more than 2,200 horse-power; while if it had belonged to the Gauloise type it might, with this pressure, attain 4,000 horse-power, as has been experimentally shown in the Gauloise.

Altogether, the last experiments in the armored Ocean squadron have brought clearly and thoroughly to light all the defects we had charged upon the engines recently introduced into the Imperial marine, and justified the conclusions we had formed. A single one of these conclusions, (that one *à fortiori* in favor of our opinion,) has not been found exactly in accordance with the facts. It is that relating to economy of fuel. In view of precedents, we had asserted that the consumption of fuel for the whole amount of steam generated would be about the same in both types. In actual experiment the *Gauloise* showed a marked advantage over the *Savoie*. In view of results so complete and convincing, we need not wonder that the superior commission expressed itself as follows at the announcement of its conclusions: "The facts speak for themselves. The comparisons of the three types of engines have, in the opinion of the superior commission, demonstrated the advantages of the three cylinders with direct admission of the steam, &c."

Since "the facts speak for themselves," we shall add nothing to our argument, and conclude by saying that the conversion of all the Savoie and Friedland engines into the other type, with three independent cylinders, should be no longer deferred.

Vice-Admiral Labrousse.

A NARROW GAUGE RAILWAY.

THE BRÖELTHAL VALLEY LINE—TWO FT. SEVEN IN. GAUGE—PARTICULARS OF THE ROAD, ENGINES, CARS AND WORKING.

Compiled from "Engineering."

The railway connecting the valley of Bröl with that of Sieg, near Cologne, of which we propose to give some particulars, is of interest to engineers not only on account of the narrowness of its gauge, which is 2 ft. 7 in., but also on account of the success with which its working has been attended. The line leaves the Cologne and Giessen Railway, at Hannef, and with the exception of a short length near that station it is constructed along the line of the ordinary road, the administrative authorities having permitted a width of about 4 ft. 8 in. to be taken from the latter for the purposes of the railway.

The Bröelthal valley line was originally designed exclusively for the accommodation of the mineral traffic to the works of Friedrich-Wilhelm-hutte; but the inhabitants of the surrounding districts found it to be to their interest to employ the line for the conveyance of their goods, as the cost of transportation was found to be about 66 per cent cheaper than by the ordinary roads; and as a result the line has at the present time a considerable general goods traffic. The main portion is about $12\frac{1}{4}$ miles in length, and with the exception of about $\frac{5}{8}$ mile is constructed, as we have already stated, along the ordinary road. At a station called Schöneberg, a branch about $1\frac{1}{2}$ miles in length extends to Sauerbach. The company are also on the point of extending the main line from Ruppichteroth to Waldbröl, a distance of $6\frac{1}{4}$ miles; and as this portion of the line cannot be constructed along the ordinary road, the Prussian Government have granted the company a subvention of 60,000 francs (£2,400), in return for which the company have engaged to establish a passenger service over their whole system. The stations on the main line are eight in number. Besides these there are watering stations for the supply of the locomotives. All the buildings are of the simplest kind, and the arrangements for supplying water to the locomotives consist simply of wooden cisterns filled by hand pumps.

The railway follows exactly the course of the road, and it includes curves of 38 meters (124 ft. 8 in.) radius, and inclines of 1 in 80. The line is always carried on the most dangerous side of the road, and it occupies a width of 4 ft. 8 in., the total width of the road being 24 ft. 9 in. Permission has also been given, in case of a new line being laid down, to increase the width occupied to 6 ft. The upper sides of the rails are on a level with the footpath, and at intervals channels are provided for the escape of the drainage water. Near Hennef, the line, together with the road, passes over the river Sieg on a wooden bridge, which was constructed at the expense of the company, but of which they keep in repair only that portion traversed by their line, paying for the maintenance of the remainder an insignificant annual sum.

At Hennef the Cologne and Giessen line is above the level of the surrounding soil, and a siding serves to conduct the larger wagons to hoppers, into which the minerals are discharged, and from which they are delivered into the wagons of the Bröelthal valley line. At the basement of the range of hoppers are the goods offices, and a running shed and turn-table for the locomotives, and a weighing machine.

The line is worked by two small tank locomotives, these engines running alternate weeks. These locomotives were constructed at Carlsruhe. They have six driving wheels in a rigid frame, and outside cylinders. The principle dimensions are as follows:

	ft.	in.
Diameter of cylinders	0	$10\frac{13}{16}$
Stroke	0	10
Diameter of wheels	2	$3\frac{1}{4}$
Distance between centers of leading and driving wheels	3	$8\frac{1}{8}$
Distance between centers of driving and trailing wheels	2	11
Total wheel base	6	$7\frac{1}{8}$
Diameter of barrel of boiler	2	$9\frac{7}{8}$
Number of tubes	73	
Length	5	7
Diameter	0	1.38
Length of firegrate	2	4
Width	1	$6\frac{1}{2}$

Heating surface.

Tubes	147 sq. ft.
Fire-box	27 "
Total	174 "

Area of fire-grate	$4\frac{1}{4}$ sq. ft.
Pressure of steam	90 lb. per sq. in.
Weight of engine in working order	$12\frac{1}{2}$ tons.

The wagons employed on the line are almost all of the following dimensions, etc.:

		ft.	in.
Length of body		10	2
Width		4	8
(In the new stock this width will be increased to 5 ft. 4 in.)			
Mean depth of body about		5	3
Diameter of the wheels	2 ft. $6\frac{3}{4}$ in. to	3	1
Wheel base	4 ft. 6 in. to	5	2
Diameter of axles	3 in. to	0	$3\frac{1}{2}$
Weight empty	$2\frac{1}{2}$ tons.		
Load carried	5 "		
Total weight loaded	$7\frac{1}{2}$ "		
Weight per wheel	$1\frac{7}{8}$ "		
Cost per wagon	£56 to £92.		

The bottoms of the wagons incline from the center downwards towards each side, so as to discharge the minerals through side doors. The longitudinal frames of the wagons are of iron of channel section; and the springs are arranged, as usual, above the axle boxes, the latter being protected by flaps of leather or canvass, as on ballast wagons, to prevent the dust from the minerals, when the latter are discharged, getting to the bearings. The wagons have central buffers placed above the draw hooks, each buffer rod being connected with the corresponding draw bar by a lever, so that the draw spring serves also as a buffer spring. The draw springs are of india-rubber. Some of the wagons have cast iron disc wheels without tyres, whilst others have wheels of the ordinary kind with tyres of puddled steel. At first the wagons were run with one wheel of each pair loose on the axle; but the results were not found to be satisfactory, and the plan was therefore abandoned.

The line is laid with rails of the following dimensions: Depth of rails, $3\frac{1}{8}$ in.; width of the top table, $1\frac{5}{16}$ in.; width of base, $2\frac{5}{8}$ in.; thickness of the web, $\frac{7}{16}$ in.; weight, from 22 lb. to 26 lb. per yard. The rails vary in length from 14 ft. 9 in. to 21 ft. 8 in., and they are carried upon transverse sleepers of oak, 4 ft. 2 in. long, 6 in. wide, and $5\frac{1}{8}$ in. deep, placed at a distance apart of 2 ft. from center to center. In the case of the sleepers at the joints, the width is increased to 8 in. The rails are secured to the sleepers by spikes, and they are connected by fish-plates $12\frac{1}{4}$ in. long, held by four bolts $\frac{1}{2}$ in. in diameter. The gauge of the line is, as we have already stated, 2 ft. 7 in., but on curves of 40 meters (131 ft. 3 in.) radius the gauge is increased to 2 ft. $7\frac{1}{2}$ in. The super-elevation of the exterior rail on these curves is from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. A trial was made on the curves of small radius of ordinary flat-footed rails, weighing 72 lb. per yard, laid without cross sleepers, but the experiment was not successful. Formerly also movable rails were used instead of the regular points; but now ordinary switches are employed. The crossings are made of hard cast iron. The extension of the line from Ruppichteroth is to be laid with rails weighing 34 lb. per yard, but the distance between the sleepers is to be increased, and they are to be placed at a pitch of 2 ft. $11\frac{1}{2}$ in. from center to center. The rails laid on the main line, between Hennef and Ruppichteroth, cost £8 18s. per ton, and the fish plates £12 12s. per ton. About 15 tons of rails and 1,000 sleepers are used annually in keeping up the line.

We must now say something concerning the manner in which the line is worked, and its commercial results. The usual load drawn by the engines consists of 28 wagons loaded with five tons each, giving 140 tons of paying load. The total weight of the train is thus, as follows:

	Tons.
Locomotive	$12\frac{1}{2}$
Wagons	70
Load in wagons	140
	$222\frac{1}{2}$

It is found that the engines can easily draw 36 loaded wagons, but the above is the usual load. The speed on the level portions of the line is a little over nine miles per hour; and in traversing those portions of the road at which there are habitations, this speed is decreased to about $5\frac{1}{2}$ miles per hour. In case of meeting a vehicle with horses not accustomed to the passage of the train, it is the rule to stop, and by means of the brakes, which are in charge of five men, the train can be brought to a stand in a distance of about 130 ft.

But one train is run over the line each way per day. This train leaves Hennef at 6 A. M., and arrives at Ruppichteroth at 8. 30 A. M., departing from the latter place at 1 P. M., and arriving again at Hennef at 4 P. M. The line is worked with but a small staff. The managing director is M. Gustorff, who resides at Cologne, and who is also the managing director of Friedrich-Wilhelmhutte, while the line is in the special charge of M. Saling, who bears the title of inspector, and whose head-quarters are at Hennef, where a book-keeper is also employed. Another sub-inspector is stationed at Schöneberg, and three men are employed in keeping up the line, one of them receiving 1.875 francs (about 18d.), and the two others 1.8 francs (rather less than 15d.) per day. The men in charge of the train, and their wages, are as follows:

	s.	d.	
1 Engine driver	3	$1\frac{1}{2}$	per day.
1 Fireman	1	8	"
1 Guard	2	1	"
4 Brakesmen, each	1	7	"

There are no signalmen employed on the line.

The merchandise transported is divided into four classes, which are carried at different charges, the goods comprised in the first class being those least liable to injury. The tariffs are as follows:

Class.	Charge per ton for the entire distance. s.	d.
1st. Minerals, limestone, etc	7	0
2d. Burnt lime, iron, bricks, etc	8	0
3d. Grain and fruits	9	5
4th. Miscellaneous. (The tariff for this class varies according to the weight.)		

The goods belonging to the three first classes are, in addition to the above tariffs, subject to a fixed charge of 4d. per ton for loading and unloading. During the year 1864 (the latest year of which we have detailed particulars) the total quantity of goods carried over the line amounted to 32,709 tons, this quantity being divided as follows:

Class.	From Ruppichteroth towards Hennef.	From Hennef towards Ruppichteroth.	Total tonnage for each class.
	Tons.	Tons.	Tons.
1st.	27,970	2,860	30,835
2d.	344	840	1,184
3d.	140	335	475
4th	50	165	215
	28,509	4,200	32,709

The total receipts for the transport of the above quantities of goods was £2,800, showing an average charge of a little over 1s. 8d. per ton; while the working expenses during the year were £1,452, of which £120 was fairly chargeable to the succeeding year. The difference between receipts and expenditure, available for interest on original cost, etc., was thus, £2,800—£1,332=£1,468. The working expenses were divided as follows:

	£
Charges for management	150
Traffic charges	188
Cost of traction	428
Station charges	177
Maintenance of way	234
Maintenance of rolling stock	216
Miscellaneous	59
	£1,452

During the year 1867 the receipts amounted to £2,584, and the expenses to £1,301, leaving a balance of £1,283 available for dividend, etc. The total cost of the line and rolling stock, etc., has been as follows:

	£
1. Permanent way of main line	9,114
2. Bridge over the river Sieg with accessory works	3,593
3. Branch line to Sanerbach	1,575
4. Stations and depots	3,363
5. Locomotives and rolling stock	4,165
6. General stores	505
	£22,317

The total cost was thus about £1,526 per mile for the total length of the line. The sum given under the fifth head is divided as follows:

	£
2 Locomotives with spare wheels	1,753
29 Wagons without wheels and axles	1,405
101 Axles with wheels	887
Accessories	28
Tools, etc	92
	£4,165

The estimated cost of the extension of the line, a distance of $6\frac{1}{4}$ miles, to Waldbröl, is £9,490.

THE SOCIETY OF ENGINEERS AND ASSOCIATES.

Without discussing, at this time, the objects and duties of institutions of engineers, we merely wish to call attention to the fact that this New York Society is in some respects differently organized from many others, and that it has in some respects done the best work of any of our societies. The movement which created the present Society of Engineers and Associates, had its origin rather in a feeling of what ought to be done in this direction, than in a conviction that the time had come when such things could be done. Its present success, however, proves that it has one essential and, among us, almost new element of life in it, viz: that its meetings are attractive. Of course the purest science and the dryest formality are the correct theoretical features of engineering meetings, but the first society in the world—the Institution of Civil Engineers in London—does not dispense with those appeals to taste, both æsthetical and physical, that are found necessary to bring men together for almost all purposes except daily and routine business. In a new country, especially when the results growing out of association for scientific purposes are not direct and immediate, the right men are few and scattered, and if not full of engagements in the evening, as well as in the day, they are glad enough to devote the few unoccupied hours to recreation. Now, a stiff meeting, in an upper room, with a bad light and worse air, is not likely to attract the overworked engineer. He may attend from a sense of duty, but as a rule the engineers' meetings of a city, thus meagerly provided with a professional home, will consist of the gathering together of two or three in the comfortable study of a fourth. But while such gatherings lack the grand element of numbers, in which there is strength, they possess the equally essential element of attractiveness. Now, by combining the two, men will come in numbers, and getting the men at stated times is three-quarters of the battle. When they see their peers about them, they will not be long in organizing ways and means to get at the information there is in them. Proceeding upon this principle, the Society of Engineers and Associates have held their monthly meetings in a parlor at Delmonico's. While the proceedings are purposely informal, rather than rigidly parliamentary, they are not aimless nor desultory. The membership is made up of the principal engine, machinery and ship-builders of the city, and there is, therefore, no lack of subjects upon which information is wanted and can be given. Nor are professional subjects alone considered. A great object is to promote good feeling among the members, and harmonious action in the business and enterprises they represent. An attractive meeting place, and an agreeable supper after meeting, are wise features of the plan. Anglo-Saxons, especially in England, find it necessary to dine together in order to accomplish any enterprise in which several interests are associated. But the parliamentary features are not wanting. There are standing committees, having chairmen and secretaries, to look after the various interests represented, and to prepare business for the general action of the Society. Thus the meetings, to which it is specially desirable to attract the talent and learning that would otherwise stay at home, are relieved from the formality of preparatory business, and the discussion of special, local, and, to the professional public, uninteresting details. At a mere nominal fee of $10 per year. proper persons not residing in New York are admitted to the Society. The annual meetings (the last Thursdays in January) are of a more general and entirely social character. The last annual meeting, at Delmonico's, called out a greater number of professional men, especially in mechanical engineering, than we remember to have ever seen collected before in this country. It included prominent builders from neighboring cities, and prominent officers of the Army and Navy, and distinguished scholars from our scientific schools. Altogether it was more like a conversazione of the Institution of Civil Engineers, in London, than any gathering that has heretofore taken place on this side of the Atlantic. In this way, in addition to its more local and business labors, the Society of Engineers and Associates is doing great good, by attracting together the right men, promoting acquaintance and good feeling, and thus *actually showing* people more in a few hours, of the usefulness and possibility of a more perfect and comprehensive organization, than could be taught them by years of individual theorizing.

LOCOMOTIVES FOR HEAVY GRADES.

A NEW SYSTEM.

Translated and condensed from Polyt. Centralblatt.

We find in the history of the locomotive not only an astonishing development of constructions, based on the principles of Trevithik and Stephenson, but also a great number of systems which, like those of Murray and Blenkinsop, affect the locomotion of the engine by means of a rail with spur-gearing lying in the middle of the track (mid-rail), or in some other similar manner, thus to enable the locomotive to ascend heavier grades. Baldwin, of Philadelphia, built in 1848, two engines according to this plan, for the Madison and Indianopolis railroad, and afterwards some engines with horizontal driving-wheels for smooth mid-rails were constructed by Sellers, for the Panama railroad. Recently, Fell made the bold attempt to construct a temporary railroad with very heavy grades and sharp curves over the Mont Cenis, in using a similar system. However, as the success of Fell's arrangements has become more and more doubtful of late, the heavy grade problem is attracting once more the attention of engineers. With a view of solving this problem, K. Wetli has published a pamphlet containing an elaborate expose of a new system, a general idea of which we intend to give our readers in the following lines:

Wetli's system has a distant resemblance to one of the older schemes of railway and locomotive construction for heavy grades. According to this older scheme, a short, strong screw, attached to the engine below its frame, and situated parallel to the track, is turned by steam-power and works itself along a concave mid-rail with oblique indentations, thus pulling the engine forward. Wetli's locomotive is also provided with a kind of a screw or rather a double worm-wheel, which, however, is placed at a right-angles to the track, its axis being about eighteen inches above the level of the rails. It consists of two strong screws, one right, the other left-handed, both fixed to the same axle, touching each other in the middle of this axle, and extending almost over the whole width of the track. This worm-wheel receives its motion by a connection with the driving-wheels of the engine. Its object is to help the engine along on steep gradients. For this purpose straight guide-rails are laid between the ordinary track-rails in a transverse position, corresponding to the thread of the worm-wheel. They are laid in couples, the two rails of each couple touching each other at an angle in the middle of the track, and reaching on the other hand the vicinity of the interior faces of the track-rails. They are nearly five feet apart. As these couples of transverse rails are strengthened by cross-beams inside the angle, the whole track has about the appearance of two parallel lines between which a succession of letters A are inscribed one above the other.

The described mechanism is not, however, intended to give motion to the engine exclusively, nor to act under ordinary circumstances. When on moderate gradients, and in favorable weather, the friction of the ordinary driving-wheels is sufficient to overcome the existing weight of the train, the engine moves on in the usual way and the worm-wheel does not touch, or scarcely touches the guide-rails. But as soon as, under less favorable circumstances, this friction becomes insufficient, a sliding of the driving wheels takes place, by which the thread of the worm-wheel is brought in contact with the transverse guide-rails, and from this moment the driving-wheels and the worm-wheel begin to work conjointly. These are the general principles of this new system, according to the account given in Wetli's pamphlet. The inventor and author further relates in an ingenious and apparently successful manner, the principal objections that might be made to his system, and finally claims for the latter the following advantages:

1. The wagons of ordinary railways can pass unaltered on the track of the new system.
2. The locomotives of the new system can pass unaltered on ordinary tracks.
3. The working capacity of the locomotive is fully utilized, because its power of traction can be and is considerably increased at the expense of its velocity at any such time and to such an extent as the circumstances require.
4. The rate at which the current working expenses rise with the greater steepness of the road, is considerably less in the new system than in the one actually in use on the Mont Cenis railroad.
5. The running of the trains is not dependent on the weather or other exterior circumstances, and all irregularities in the service of the road that might otherwise result from this cause, are thus avoided.

S.

EFFECTS OF PHOSPHORUS IN IRON AND STEEL.

From a paper read before the Chemical Society "On the Connection between the Mechanical qualities of Malleable Iron and Steel, and the amount of Phosphorus they contain," by Dr. B. H. Paul, and the ensuing discussion.—"Chemical News."

It is generally considered that very small quantities of phosphorus in malleable iron and steel are most prejudicial to the quality of the metal. Quite recently, an eminent metallurgist has stated as a fact that much less than .3 per cent of phosphorus produces a decided and injurious effect on steel. The author has, however, been unable to discover any evidence sufficient to justify such a conclusion, and still less any reasonable explanation of it. He has recently had an opportunity of testing the truth of this conclusion, by determining the phosphorus in some samples of the iron and steel made by the new nitrate of soda process from British pig-iron known to contain phosphorus. Seven bars of iron and two bars of steel, made by the Heaton process, were examined; their tensile strength and extension had been determined by Mr. Kirkaldy. The iron bars had a tensile strength of from 46,547 to 52,824 lbs. per square inch of area, and an extension, when subjected to this strain, of from 21 to 28.6 per cent of their length. The two cast-steel bars had tensile strengths of 80,916 and 106,602 lbs., and extended 3.3 and 13.7 per cent of their lengths. In the iron bars, the author found .144 to .38 per cent of phosphorus (average .237 per cent), and in the two steel bars .24 and .241 per cent. The author, therefore, thinks himself justified in asserting that the commonly received opinion on this subject does not always represent the truth.

Professor Miller has had opportunities of examining some of these steels. It fact, he might say that Dr. Paul's experiments had been suggested by himself. He had found in some careful analyses of his own, very unusual quantities of phosphorus, even in samples of high class iron—iron which worked well cold, and also at a red and bright yellow heat. It could hardly be doubted that in many statements of the composition of iron the amount of phosphorus found had been too low. The old method of estimating the phosphoric acid, which involved the throwing it down as iron-salt, was unreliable. The phospho-molybdate process, employed by Eggertz, was undoubtedly the best; but even this required the greatest care to avoid getting too low a proportion of phosphoric acid. It was very difficult to ensure the entire precipitation of the phospho-molybdate. One thing was clear from these experiments, namely, that the presence of from two to three parts of phosphorus in 1,000 of iron was not so detrimental as was generally supposed.

The President inquired how the phosphorus existed in the iron, and the form in which it was eliminated during Heaton's process.

Professor Miller could not speak with certainty of the condition of phosphorus in the iron; it probably existed as phosphide. It was, however, most certainly eliminated in the form of phosphate.

Dr. Price remarked that there was nothing new in the statement that such quantities of phosphorus might exist in wrought iron, but that with regard to steel he had yet to learn that .24 per cent of phosphorus could be present without injuring the metal. With regard to methods, he believed that the one at present in use was absolutely correct, that, namely, in which the phosphorus was separated as phosphate of iron, and then determined with magnesia. The molybdate method was excessively tedious.

Mr. Forbes said that in Sweden they would not receive for making steel, iron that contained .1 per cent of phosphorus. Many works had had to stop for want of ores that were free from phosphorus. For one mine of such ore there were ten which yielded ore containing phosphorus, and they would most gladly use it if they could. He could not agree with Dr. Miller that the amount of phosphorus in iron was under-estimated. The molybdate process was thoroughly understood in Sweden, and had been in use since 1856. Errors in the estimation of phosphorus could not be due to ignorance of that method.

Professor Miller explained that he only meant to say that the molybdate process required care. No doubt the results obtained by Eggertz were perfectly correct. In answer to the President, Professor Miller then gave a short account of the Heaton process. A quantity of the niter was placed in a wrought-iron pot lined with fire-clay; on this was put a perforated plate of iron, and 12 cwt. of melted cast iron from a cupola furnace were then introduced, with sand and lime. During the reaction, fumes, first white, then brown, next gray, were evolved. A violent flame and a roaring noise attended upon it. When again tranquil, the metal was emptied on the floor of the furnace; the slag ran out and the pasty mass was pressed between rollers. He was unable to tell the proportion of phosphorus in the slag. The crude cast iron employed contained 1.43 per cent, and the cast steel obtained under .3 per cent. A part, at least, of the phosphorus lost was certainly to be found in the slag.

Dr. Paul quite agreed with Mr. Forbes that Swedish steel was free from phosphorus. As far as he could learn, there was no other evidence in proof of the injurious action of phosphorus on steel.

DOES IRON IN BRIDGES DETERIORATE?

THE HAMMERSMITH SUSPENSION BRIDGE.

From "The Engineer."

A very interesting question has been put to the public in general, and to engineers in particular, by the Secretary of the Royal Humane Society, through the medium of the "Times." This gentleman has, it appears, remarked on the occasion of more than one boat race, that the pretty suspension bridge at Hammersmith is taken possession of by an excited crowd standing as close possibly as men can stand; and he has further perceived that on the passage of the contending boats beneath, this crowd surges from one side of the bridge to the other, and causes it to oscillate violently, as in the manner of suspension bridges on comparatively slight provocation. He has heard that in process of time iron crystallizes and becomes brittle under strain. He is aware that Hammersmith Bridge has been built a long time, and strained and shaken not a little; he fears, therefore, that the quality of the iron has been deteriorated; and dreading the consequence of the giving way of any portion of the structure during the approaching Oxford and Cambridge boat race, he wrote a very sensible letter to our contemporary, therein suggesting that the matter should be looked into a little. On Thursday week Lord Bury asked the Government, in the House of Commons, whether they intended to take any action in the affair, and was informed that the Board of Trade would send a competent engineer to examine and report upon the structure. Meanwhile one or two more letters have appeared in the "Times" on the subject, and notably one from the pen of Mr. G. Gordon Page, C. E.

It is not disputed that up to the present moment the bridge has proved itself to be strong enough to sustain any strain which sight-seers could put upon it. It has been densely crowded over and over again, and no important failure has ever taken place, nor have any but the most trifling repairs ever been needed. The assumption that an accident may follow if the public take possession of the platform on the 17th instant, rests simply on the theory that the molecular structure of the iron has been deteriorated by vibration under strain, or that the sectional area of some important members—such as the chains or the suspending links—has been reduced by corrosion. We must wait for the report of the Board of Trade engineer to settle these things. But, meanwhile, we may point out that the inquiry possesses peculiar interest, not only as regards Hammersmith Bridge, but all iron structures exposed to vibration while loaded. It has long been a vexed question among engineers whether iron does or does not become crystalline and brittle in service; and it will be no small achievement for the Board of Trade to advance our certain knowledge of the subject by the contribution of even one well verified fact. The controversy may be regarded as involving three different theories. According to one, iron invariably becomes brittle and crystalline under even the most moderate strains, provided it is kept in vibration for a sufficiently long period. According to another theory iron never becomes crystalline and brittle under any strain; and, according to the best, the metal changes its character only when strained above its limit of elasticity—that is to say, when it has been stretched to such an extent by any applied force that it will not, on the taking off of that force, return to its original dimensions. The second theory is now almost universally rejected as untenable by competent engineers. It is excessively difficult to prove which of the remaining two is right and which is wrong, for the following reasons: In the first place it is impossible to tell the exact strength of a bar without testing it till it breaks. Therefore it is not easy to determine whether any bar has been weakened by age and molecular change or not. We may try a bar now and find that it will stand eight or nine tons per square inch without permanent set. We may put this bar in use, test it at the end of twenty years, and find it stand just what it did before; but it by no means follows that this circumstance proves that no deterioration has taken place. To assume that the facts supported this latter theory, is to assume that the original test was as nearly as possible all that the iron would bear, so that no margin was left for deterioration, which might or might not be true ; but it is as we have said, practically impossible to test, in the first instance, any bars used in a structure like the Hammersmith Bridge, right up to the last limit without going beyond it. In the second place it is difficult to prove that a bar has deteriorated by any examination of the structure. Those who believe in the deterioration under vibration theory, maintain that the iron loses its fibrous nature, becoming crystalline and brittle. The assumption of deterioration is based on the presence of a crystalline internal structure in the bar, which it is believed the bar did not originally possess. Now it so happens that we know less probably about the internal structure of iron than about that of any other substance used in the arts. We never see anything but its outside. Break or cut an iron bar as we will, still we are on the surface. Thus, as is perfectly well known, a bar 10 ft. long can be broken into ten pieces, showing alternately a fibrous and a crystalline fracture. Moreover, it does not follow that fibrous iron must be stronger or better than crystalline iron. It is quite true that rails, axles, chairs, etc., which have broken after long service, usually give a crystalline fracture, but it has never been proved that we are not confounding cause with effect when we say that the rail or the axle was broken because it had become crystalline. It may be just as correct to say that the rail had become crystalline because it was broken, for anything proved to the contrary. Of course we do not mean to assert that the structure of iron or steel does not change during use, or that these metals do not deteriorate in service, for this is contrary to fact. We only desire to point out that it has not been definitely proved that iron becomes crystalline when caused to vibrate under strain; or that, assuming crystallization does take place under such conditions, it follows that the iron has become weaker because it is crystallized. Whether it is brittle because it has changed to the crystalline from the fibrous condition, or whether it has changed from fibrous to crystalline because it has become brittle, no one can say with absolute certainty. The brittleness is demonstrable, the cause is not. It has been argued, indeed, and with some show of reason, that there is no such thing as congenitally fibrous iron, but that fibrous fracture merely results from the drawing out and rearrangement of certain previously interlocking crystals when the iron is broken under test, just as an apparently amorphous mass of felt may be resolved into its constituent fibers by careful carding. The theory is not ours, and we neither endorse it nor dispute it. We cite it simply to show that there is at least one way of reconciling difficulties connected with the appearance of the fracture of iron.

As regards the examination of Hammersmith Suspension Bridge, we wish it to be borne in mind that even should the test bars, which we suppose will be taken from the structure and broken, show a crystalline fracture, the circumstances will not prove molecular deterioration. Neither will the presence of a fibrous fracture prove that the structure is perfectly safe and trustworthy. The point to which the Board of Trade engineer should devote his attention, is the degree of elongation manifested by the bars before fracture. If this is not considerable, it may be taken for granted that the iron has deteriorated, whether the fracture is or is not crystalline, because the bridge was built almost before hot blast iron was known; and there can be little doubt that whether very strong or not, the materials of Hammersmith Bridge were well made and originally ductile in a very high degree. If the inquiry is properly conducted, its results will prove very valuable. The least carelessness will render them useless.

Mr. Page's letter, to which we have before referred, contains certain interesting statements worth reproduction. Quoting a report by Professor L. D. B. Gordon, dated August 7th, 1862, he writes: "Hammersmith Bridge was erected in 1827; Engineer, W. Tierney Clarke. Total length between land abutments, 710.7 ft.; useful width of road, carriage-way, 20 ft.; two footpaths, each 5 ft.; total width, 30 ft.; span of main opening, 422.5 ft.; ratio of versine to span, 1-14.31; the total section of chains at the towers, 180 square inches; weight of a superficial foot of roadway, 63 lb."

As a matter of fact the bridge was completed in 1824, not in 1827. Mr. Page goes on to say that "Drewry, an authority on suspension bridges, states that the bars of the chains were proved up to nine tons per square inch. The greatest possible load has been assumed by Mr. E. Clark at 80 lb. per superficial foot, but this has been considered as excessive by many engineers. An experiment was made, which came under my notice, by packing men on a weigh-bridge, with a result of 84 lb. per superficial foot; but it is not within the limits of probability that such a crowd could accumulaté on any bridge. I gather from various authorities that 70 lb. per foot superficial may be assumed as a standard for the load that the platform of a bridge could contain. Such a load on Hammersmith Bridge would produce a strain on the chains of 8.86 tons, or 1.4 tons below proof strain."

Inasmuch as the maximum strain now allowed by the Board of Trade is but five tons, it is evident that the structure is nearly 45 per cent weaker than these regulations allow; and we confess that we think the apprehensions—the expression of which has led to the official inquiry—are very well founded.

We cannot better conclude this article than by appending a few particulars regarding the construction of Hammersmith Bridge, in addition to those given above, by Professor Gordon. His dimensions are substantially correct. The deflection of the main chains in the centre is 29 ft. 3 in. The tension on the iron at the points of suspension is 1.857 times the entire suspended load. The piers are of stone, 22 ft. thick, 42 ft. wide at the top, 72 ft. at the waterline, and 48 feet high, measuring from the carriage road. There are eight main chains, arranged in four double lines, two small chains being put one under the other on the outside of each footpath, and two principal chains on each side of the carriage way. The small chains each consist of three rows of 1 in. flat bar links, 8 ft. 10 in. by 5 in. wide, coupled by $2\frac{3}{4}$ in. round bolts, and covering plates $15\frac{1}{4}$ in. long by 8 in. broad and 1 in. thick. The large chains consist each of six similar rows of plate links. The vertical rods are 1 in. square, and stand 5 ft, apart.

THE ELLERSHAUSEN PROCESS.—Some very careful experiments have recently been made at one of our large ironworks. In order to test several kinds of iron, and to determine the waste with accuracy, the iron was melted in a cupola and afterwards weighed. Several varieties of ore were used. Analyses of the material at different stages are being made. We shall publish the results.

AMERICAN LOCOMOTIVES AND ROLLING STOCK.

From a paper by Zerah Colburn, before the Institution of Civil Engineers, March 9th, 1869.

In construction and working, the American railways represent little more than a modified application of English practice. When the systems of the railway machinery of the two countries are compared, many of the differences which first strike the eye are found to be external, rather than fundamental; and so, too, many of the peculiarities of construction now retained in America are due to the initiative of English engineers.

Pursuing the history of the introduction of locomotives into the States, it was observed that the first two worked in America were made in England in 1828, one by Mr. George Stephenson, the other by Mr. J. U. Rastrick. In the same year the engineers of the then contemplated Baltimore and Ohio Railroad visited this country, when Mr. Robert Stephenson suggested to them what was now the distinguishing feature of all American railway rolling stock, viz, the bogie, to be applied to the engines intended to work round curves of six chains radius, at that time proposed to be adopted. The bogie, which had grown out of William Chapman's invention of 1812, was then, Mr. Stevenson stated, in regular use upon the quays of Newcastle. Having regard to the character of the lines first constructed in the States, it was essential that the locomotives should be light and cheap, and the first engines made there, between 1830 and 1832, weighed only from three and a half tons to four tons. Some of the English-built engines imported at about that time had their leading wheels removed, and a swiveling bogie substituted. The bogie was not, however, exclusively employed. Considerable numbers of engines made by Messrs. Stephenson & Co., Messrs. Bury, Curtis & Kennedy, Messrs. George Forrester & Co., and Messrs. Braithwaite & Co., were afterwards imported, and worked as originally constructed; and, as late as 1855, at least one hundred locomotives of English construction, or made almost exactly upon Messrs. Stephenson's plans, could have been counted at work in the States. For many years wood only was employed as fuel, and as it produced great quantities of sparks, as annoying to passengers as they were dangerous to goods, much ingenuity was directed to the problem of separating and withholding them from the escaping smoke and steam; and the voluminous "spark arresters" were very successful in this respect, while they gave an individuality to the engines. Again the rigor of the American winters compelled the adoption of some kind of shelter for the enginemen and firemen; and this was afforded by the bulky, and often extravagantly painted "cabs," which imparted a novel appearance, but without in any way affecting the principles, or economical conditions of working, of the engine.

As high speeds were seldom attempted upon the early American lines, the greatest steam tractive power was sought and obtained, both by working high pressure steam and by employing driving wheels of small diameter. Thus, although, in 1835, the English built engines, and those copied from them, were worked at 50 lb. pressure, and had 5 feet driving wheels, it was not long before American practice settled upon 90 lb. to 100 lb. pressure and 4 ft. or even 3 ft. 8 in. driving wheels. It was soon found, however, that the adhesion weight upon a single pair of wheels, necessary to work up this increased steam tractive force, was too great for the strength of the way, and coupling was then resorted to; and now, with the exception of a few light tank engines on branch lines, there was not probably an engine in the States having single or uncoupled driving wheels. Four tons might be said to have been the maximum per wheel for many years, while three tons was the more usual average.

Compensating levers were now employed on all American engines, whereby the weight was not only equalized between the coupled wheels, but the effect of a jolt upon one pair was divided and distributed, through the springs and levers, upon the other pair. For some years, too, bearings of the outer ends of the springs of the coupled wheels were made to rest upon india-rubber blocks.

The details were then given of several descriptions of engines long worked on the Baltimore and Ohio and Reading railroads, as well as of those employed to work the incline of 1 in $16\frac{1}{2}$ and $1\frac{1}{4}$ mile long, at the Madison terminus of the Madison and Indianapolis railway. Compared with English practice, in which six-wheeled coupled engines had from 5 tons to 6 tons on a wheel, and eight-wheeled coupled engines had 7 tons on a wheel, it was observed that the subdivision of weight in American engines was carried about half as far again, or, in other words, that they averaged only about two-thirds as much weight per wheel, and that they thus required, for a given total weight, half as many more wheels. Except with smaller wheels, this could not be done on any practicable length of wheel base; but none of the American goods and bank engines, of which the particulars had been given, had wheels larger than 3 ft. 11 in. in diameter. There were objections also, of much weight, to coupling a larger number of wheels from a single pair of cylinders. It was more or less difficult, if not impossible, to preserve an exact equality in the diameter of the wheels, an exact parallelism of the axles, and exact equality in length of the coupling rods. The extent to which coupling had been carried in American goods engines had been due, in a great measure, to the following expedients. The coupled wheels were as equally loaded as possible; their tyres, in a majority of cases, were of chilled cast iron, since replaced by steel; and the former were cast, and the latter turned, nearly or quite to a cylindrical form, or with but little or no cone. The driving wheels were the middle pair, or, in the case of an even number of pairs, one of the pairs nearest to the mid-length of the wheel base; compensating levers were employed, and adjusting wedges had for some years been applied to the axle-boxes. The coupling rods, in many cases, were made without brasses, round steel bushings being fitted to circular eyes formed at the exact required distance apart in the ends of the rods. With the exception of the leading and trailing wheels, the coupled wheels were generally fitted with plain cylindrical tyres having no flanges. Outside coupling cranks, necessary with outside frames, had rarely been employed, and were never so now. The coupling rods were counterweighted within the wheels themselves, no attempt being made, in inside cylinder engines, to set off their weight against that of the cranks and attached parts. In other words, the coupling pins of the driving wheels were coincident, on each side of the engine, with the position of the crank in inside cylinder engines, and, of course, necessarily so in outside cylinder engines. The experience of American locomotive engineers had been to the effect that with this arrangement, which was the opposite of English practice, the axle-boxes wore more uniformly, and that there was less "knocking" where a little play in the horn plates had once begun. And lastly, the length of the crank being one-half the radius of the small coupled wheels employed, any inequality in the length of the coupling rods was attended with less slipping and binding than where, with larger wheels, the crank was but about one-third the radius of the wheel.

The general form of passenger engine now in use in the States was then described. It had in most cases outside cylinders—indeed, inside cylinders had not been built for many years—and it had invariably four coupled driving wheels and a four-wheeled bogie. The leading dimensions of the representative type of passenger engines were: cylinder from 15 in. to 17 in. in diameter, with a length of stroke of from 22 in. to 24 in., and coupled driving wheels of from 5 ft to 5 ft. 8 in. in diameter. Such engines would exert a tractive force of $3\frac{1}{2}$ tons to 4 tons in starting, for which their adhesive weight, assisted sometimes by sand, was sufficient; and thus they could get quickly away from stations, even with trains of a gross weight of 200 tons or more. Economy of fuel had not been studied to the same extent in American as in English locomotives: the blast pipes of the former were smaller, the draught more forced, the back pressure greater, and less expansion was attempted in the cylinders, the link motion being generally arranged to cut off at one-third stroke as a minimum, and at nine-tenths, or more, as a maximum. It was thus that boilers of moderate size were made to supply steam for work equal to 300 indicated horse power, or the exertion of upwards of 2 tons of draught upon a passenger train at a mean speed of 25 miles an hour; but there was nothing remarkable in the consumption of from 50 lb. to 60 lb. of coal per mile in such work. It was stated that on the Pennsylvania Central railroad—a line 356 miles long, with gradients of 1 in 100 and 1 in 55—the consumption of coal for both goods and passenger trains amounted on an average to about 70 lb. per train mile, the goods mileage being three and a half times the passenger mileage. The coal was of excellent steaming quality, and cost about $3\frac{1}{2}$d. in currency, or $2\frac{1}{2}$d. in coin, per train mile. At this rate a difference in consumption of 24 lb. of coal per mile would only cause a variation of 1d. per mile in the cost of fuel; and it had been argued that such a waste was better than the alternative of employing an engine 4 tons or 5 tons heavier, to work with a less rapid rate of combustion, a slower piston speed, and more expensively.

The goods engines were moderate in weight, had large cylinders and small wheels, and drew heavy trains at a fair speed, with a consumption of coal often amounting to 100 lb., or more, per mile. On the Pennsylvania Central railroad the standard type of this class of engine had ten wheels, of which six, each 4 ft. 6 in. in diameter, were coupled. The whole weight of the engine was only $31\frac{1}{8}$ tons, and of this but $23\frac{1}{2}$ tons rested on the coupled wheels, available for adhesion. The cylinders were 18 in. in diameter, with a length of stroke of 22 in. With 60 lb. mean effective pressure per square inch upon the pistons, those engines would exert a tractive force, less their own internal resistances, of rather more than $3\frac{1}{2}$ tons, or about one-seventh their adhesion weight, although in starting a train, or in ascending a gradient, with 100 lb. pressure on the pistons, the steam tractive force would be 6 tons, equal to more than one-fourth of the adhesion weight, the efficiency of which would then be assisted, when necessary, by sand. Details of the performance of some of these engines were next given. In one case, after allowing for gravity $8\frac{5}{8}$ lb. per ton, for a train, engine and tender included, of 1,040 tons weight, the total resistance would be 4 tons, and thus the work done on each mile was calculated to be equal to 24 horse power exerted for one hour; and if the estimates could be trusted, the consumption of coal per horse power per hour would not exceed $4\frac{1}{4}$ lb. to $5\frac{1}{4}$ lb. The speed probably was not more than 15 miles an hour, corresponding to 360 horse power. The policy of American railway managers, with respect to goods traffic, as it was also the policy of the managers of most of the French lines, was maximum loads at slow speeds, involving a minimum resistance per ton, and correspondingly a minimum working expenditure per ton.

No experiments upon the dynamical efficiency of American engines had been made, so far as the author was aware; but he had run an experimental train on the Erie railway, over the whole length of the line and back, a total distance of nearly 900 miles. The same engine was employed throughout the run, occupying in all nearly three weeks, making an average for each week day of about fifty miles. The results of these experiments appeared to show, that the resistance of bogie rolling stock, even under disadvantages, was less than that of English rolling stock, as ascertained by the best authorities, and also that the rate of adhesion to weight averaged considerably more in the States than in England. With respect to adhesion, as the surfaces in contact were identical with those on English railways—indeed the rails and tyres in general use in the States were commonly of English manufacture—any difference in this respect must be attributed partly to the influences of climate and partly to a better application of sand, when necessary to increase the bite upon the rails. The sand was dropped equally upon both rails, not in intermittent handfuls down a pipe on one side of the engine only, but by means of the hand gear and regulating valve since adopted on the North London Railway. The experiments in question were, no doubt, influenced by the favorable circumstances of weather, and something was to be allowed also for the great length of train drawn, very long trains having a less tractive resistance per ton on a level than short ones, and something, possibly more than was commonly supposed, might have been due to the use of oil-tight axle-boxes, the saponaceous compound known as "railway grease" being nowhere in use on railways in the States. Messrs. Guebhard and Dieudonné's experiments, made in 1867, on the Eastern Railway of France, showed a considerable diminution in the resistance of oil-boxed rolling stock, as compared with that fitted with grease boxes.

Of the mechanical details of American locomotives, considered apart from the details already touched upon, much might be said. There were differences, and they were numerous, but they involved no important principles. The chilled cast-iron wheel, however, for engine and tender bogies, and especially for carriages and wagons, deserve mention. No wrought iron wheels, so far as the author could learn, were now employed in the States, unless in a few cases for engine driving wheels; and wrought iron wheels, at first exclusively adopted, had been wholly abandoned on the Grand Trunk and the Great Western railways of Canada. The cast iron wheels were not only much cheaper, but they were more durable, and, if not safer, were at least equally safe. The wheels employed for passenger carriages were 2 ft. 9 in. in diameter, and weighed 5 cwt. The bogie wheels of engines, tenders, and goods wagons were generally 2 ft. 6 in. in diameter, and varied in weight from 4 cwt. to $4\frac{1}{2}$ cwt. They were cast of special mixtures of the best qualities of iron, the requisite conditions being great absolute strength to resist both sudden and progressive strains, and the property of taking a deep and uniform chill. But little of the cast iron employed for wheels had a tensile strength of less than fifteen tons per square inch, and it broke with a fracture, almost suggestive of fiber, and of a dark gray color, but when chilled of a silvery whiteness. The chilled wheels ran from two to six and even seven years, according to the traffic, before becoming so much worn as to require removal, representing a service of from 80,000 miles to 200,000 miles. Engine driving wheels of from 4 ft. to 5 ft. in diameter, had been cast with chilled faces, thus requiring no tyres, and chilled tyres, from 4 ft. to 6 ft. diameter and $3\frac{1}{2}$ in. thick, had been extensively and successfully employed at fair rates of speed, say 28 miles an hour.

Wood was almost exclusively employed as fuel, except upon two or three important lines in the coal districts, until within the last ten or twelve years. Iron fire boxes and copper tubes were then generally adopted; but for burning coal, steel fire boxes and iron tubes were now used. Of upwards of four hundred steel fire boxes in the engines of the Pennsylvania Central railway, some had been in use for six years or more. The tubes were set without ferules, and very little trouble, as the author was informed, was experienced either from leaking or cracking. It was worthy of observation, that the evil of "furrowing," by no means uncommon in this country, was unknown in the States, and no other explanation appeared available, than that the thinner iron employed there permitted of a certain elasticity in the structure of the boiler, sufficient to prevent the localization or accumulation of bending or other strains at particular points, or rather upon particular *lines* of resistance.

What were now understood as steep, or exceptionally steep, gradients were rare in the States. Some instances of such were cited, and it was mentioned that, in July, 1836, one of Norris' engines, weighing 6 tons $8\frac{1}{2}$ cwt., and drawing behind it, including tender, a load of 8 tons $11\frac{1}{2}$ cwt., ascended an incline near Philadelphia of 1 in 14, and 933 yards long, at an average speed of $15\frac{3}{4}$ miles an hour. The nominal weight on the driving wheels was $3\frac{1}{2}$ tons, but it was believed that a portion of the weight of the tender was made to bear upon the foot plate, thus increasing the adhesion.

With regard to the expense of maintenance, it was stated that the average cost of engine repairs in the States, exclusive of those renewals which amounted to building a new engine, might be taken as a maximum at 10 cents currency per train mile, equal to $3\frac{3}{4}$d. in coin. Of this, the absolute difference in the cost of labor and materials would account for nearly or quite 1d., leaving $2\frac{3}{4}$d. to 3d. as the cost at English prices. Again, the manner in which these repairs were conducted showed a want of system and organization, and the shops were not fitted with some of the appliances considered essential in this country. Whatever economy in repairs might attach to the American engines was due, after allowing for the moderate working speed, to three causes only, viz: the use of the bogie, of chilled cast iron bogie wheels (which could be renewed at a cost of from £2 to £2 10s. each, after allowing for the value of the wheel taken out as old iron), and of steel or iron fire boxes and iron tubes. About twelve or fifteen years ago, the average mileage of American engines, taking the full stock of the leading lines, was not above 15,000 miles yearly—now it was probably not far short of 20,000 miles, and on some lines it might be even more.

There remained the consideration of the carriage and wagon stock, with reference to its mechanical peculiarities and its commercial relation to traffic. The earlier American carriages were made upon the English model, but it was found not only that a short wheel base was required for six chain and nine chain curves, but also that side buffers aggravated the difficulty. The bogie, already in use on the engines, was, therefore, adopted for the carriages, and it was soon discovered that the length of body could be considerably increased, and that the longer it was the steadier it became. But the long bodies precluded the use of side buffers, and so the central buffer with a loose coupling took their place. End doors afforded an obvious means of economy in the structure of the carriage, and left the whole depth of the body below the window sills available for any combination of trussing, most effective for carrying out a comparatively long span. The end doors, with a continuous passage throughout the carriage, afforded obvious facilities for communication. The central passage required an additional width of carriage, and from 9 ft. to 9 ft. 6 in. was a common outside width; while in some cases, even on the narrow gauge, a width of more than 10 feet had been adopted. These widths allowed seats for four passengers across, and for the longitudinal passage dividing the seats. The seats had reversible backs, so that the passenger might face either way, the carriages running in either direction without turning. It was undeniable that the seating was not so roomy and comfortable as in an English first-class carriage, and that, as compared with a second-class carriage, there was a certain loss of space. It was equally undeniable that such carriages could never answer for short traffic lines, where forty, fifty, or more passengers had to leave, and as many more to enter, in a minute or a minute and a half. The long body, however, with end doors and platforms, possessed obvious mechanical advantages. Its length gave steadiness, and the depth below the window sills afforded ample opportunity for providing vertical stiffness without undue increase of weight. There were no cross partitions; there were but two doors where English carriages would require, for the same number of seats, according to class, from twelve to twenty-six; there was much less sash and glazing, while there was at the same time more light; there was an important saving in respect of draw-springs, buffers, buffer-rods and screw couplings, and there was every facility for applying brakes, as was always done in the States, to every wheel in the train, either from the platforms of the carriages themselves or from the engine. It was an advantage of the long body, with its corresponding weight and number of wheels, that the application of the brakes, however suddenly, did not produce the jolting of which passengers complained so much when the same thing was attempted upon English carriages. Passenger carriages upon the double bogie plan were made of various lengths, from 45 ft. to 60 ft. exclusive of the additional 2 ft. 6 in. at each end for platform and covering porch. They accommodated from sixty to eighty-four passengers, and weighed, empty, 12 tons and upwards, or from 16 tons to 22 tons loaded. Some notice was next given of Pullman's hotel car, and of the carriage built by the Messrs. Winans for the Emperor of Russia. The improvements which had been effected in the engine and other bogies were then alluded to, and a description was given of the oil-tight axle-box, as well as of Loughridge's and of Creamer's continuous brakes.

In comparing the cost of maintenance of American carriage and wagon stock with that on English lines, many considerations were to be regarded. To say that the cost, in

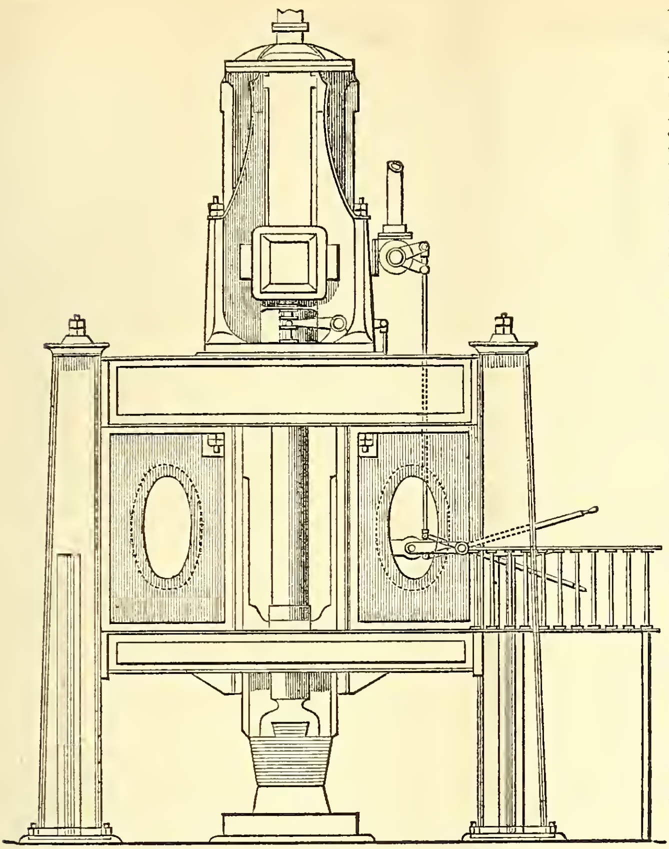
1867, on the 1,612 miles of railway in the State of Massachusetts, for a train mileage of nearly ten million miles, was 6.55 cents currency, or about 2½d. coin, per train mile, did not permit of any accurate deductions. In the States, the average number of passengers continuously carried over the whole distance made by a train was generally one-half greater than in England, although the proportion of dead weight to live load was probably nearly as high as in this country; the speed was less, and there remained the fact that labor and nearly all materials were much dearer. On the other hand, there was a considerable saving in the use of chilled cast iron wheels, such a thing as a wheel-turning lathe, for carriage or wagon stock, being unknown in the States; the maintenance of buffer and draw springs cost much less; the maintenance of the carriage bodies was cheaper, from their greater strength and simplicity of structure, and from the fact that there were no side doors to slam.

One objection to the use of chilled cast iron wheels, not referred to in the earlier portion of the paper, was that, being almost necessarily of the disk form, their weight increased in a ratio nearly as the square of the diameter, and thus the largest railway carriage wheels yet employed in the States were but 3 ft., and this size was long ago discontinued in preference for 2 ft. 9 in. In the case of cast iron spoked wheels, the chill was less hard opposite the ends of the spokes than elsewhere, and thus they soon showed flat spots.

It might be said, in conclusion, that if American railway practice were in any or many respects more daring than that which prevailed in this country, failure, if not too often repeated, was regarded in the cousin country as a misfortune, where here, unless it proceeded from causes absolutely beyond prevision, it was rightly regarded as a fault, a misdemeanor, or even a crime.

THE RAILWAY FERRY ON THE LAKE OF ZURICH.—The "Neue Zürcher Zeitung" gives some farther particulars of the work, which was generally described in "Van Nostrand's Magazine," No. III, page 208.—When the idea of a steam ferry was adopted, Mr. John Scott Russell, civil engineer and naval architect, was charged with making the necessary designs for it. Mr. Russell built, twenty years ago, the first steamer put upon the Lake of Zurich for the steamboat company at Schaff'hausen, and this steamer is considered up to the present day as one of the best crossing that water. The contract for the execution of the ferry boat was entrusted to Messrs. Escher, Wyss & Co., of Zurich, after a competition with several of the first class firms of England, France, Germany and Switzerland. The work was begun in January, 1868, at the works of the abovenamed firm at Stampfenbach, and the ferry boat was launched in the following October. For its propulsion a steam engine of 200-horse power (nom.) is employed. The fixed works required at the two ports, including two steel bridges (also designed by Mr. J. Scott Russell), in order to establish a direct communication between the shore stations and the ferry boat, had already been executed in Friedrichshafen under the direction of Mr. Brockmann, engineer of the Wurtemburg Railway, and in Romanshorn, under the direction of Mr. Seitz, engineer of the North Eastern Railway of Switzerland. These steel bridges are fixed at one end, which is on the same level as the rails in the stations, whilst the other end can freely move up and down in order to correspond with the level of the rails upon the boat, as conditioned by the different heights of the water of the lake, which varies at different seasons. These bridges and the ferry boats are provided with two lines of rails in order to carry at the same time two trains across the lake. The ferry boat itself is constructed strong and stable enough to resist even the most violent storm; its bottom is flat, and its upper works are partly covered in by a roof, which forms also a deck, from which the captain directs the course, and which may be also used by the passengers of the railway trains as a pleasant lounge during the passage. The time of crossing the lake is about one hour, and there exists no reason why other lakes in Switzerland, many of which are 50 to 60 kilometers long, should not be crossed in the same manner. The working expenses of such a system are not higher than those of a first-class railway, and the velocity may be increased from 20 to 25 kilometers per hour. The lakes would thus no longer constitute a severance between two districts or countries, but would become highways for increasing the traffic and for facilitating the communication.

We are glad to find, says the authority quoted, that Mr. John Scott Russell's abilities, which his countrymen, at least those of the world of science, cannot forget, thus appear to continue to find useful and congenial application.



Fifteen-Ton Steam Hammer for the Russian Government.—The engraving represents a so-called "50-ton" double-action steam hammer, which has been constructed by the Kirkstall Forge Company, Leeds, to the order of the Russian Government. The hammer frame, as will be seen, is, with the exception of the cylinder, constructed entirely of wrought iron plates. The valve gear is so arranged that the hammer can be driven at either side. Steam is admitted to the cylinder by an equilibrium slide valve, a conical valve being fitted into the upper passage, admitting either the exhaust steam from the under side of the piston, or the full pressure from the boiler to the top side when required, so that the hammer may either fall by its own gravity with the pressure of exhaust from the underside of piston added, or the blow is increased by the admission of full steam from the boilers. The piston and rod are forged in one piece, which, together with the hammer, weigh 15 tons. The cylinder is $46\frac{1}{2}$ in. diameter and 8 ft. stroke.—*Mechanic's Mag.*

Large Hydraulic Testing Machine.—Messrs. William Sellers & Co. constructed, some seven years since, a testing machine for the Pennsylvania Railroad Co., after the designs of J. H. Linville, Esq., President of the Keystone Bridge Co. The following are the principal dimensions: Piston, about $18\frac{3}{16}$ diameter; 260 sq. in. area; stroke, 2 ft.; thickness of ram about 9 in. The machine is mounted on a foundation of masonry 75 ft. in length. In front of the ram, and 29 ft. from the cross head, which is mounted on wheels and propelled by the piston, is another fixed cross head, coupled to the ram by 12 bars of iron 7 in. $\times$ 1 in. At this end of the machine, by use of differential blocking pieces, any sized specimen, up to 3 ft. diameter and 28 ft. in length, can be subjected to a pressure of 675 gross tons.

To the cross head in front of the piston is coupled a similar cross head, mounted on wheels in rear of the ram. Compression beams, 4 ft. in length, are secured to the masonry, with a movable cross head secured in notches in the compression beams. This end of the apparatus is used for testing large bars, to determine their tensile strength, and is now coupled to the forward cross head by bars proportioned to withstand a tensile stress of 130 gross tons. The pumps are double acting, with large and small piston for light and high pressure. The machine is supplied with two of Shaw & Justice's mercury gauges, and two spring gauges, also a weighing lever. For the last two years this machine has been in use at the Keystone Bridge Works and Union Iron Mills, Pittsburg, where the iron for all the Keystone Company's bridges is tested. The machine described in this Magazine (No. 4, page 346) is not, therefore, the largest in the country, and is similar to, but smaller than the machine, above described, which has been in constant use for seven years.

HISTORY OF DECARBURIZING IRON.

No. III.

The titles only of letters patent of the United States, prior to 1848, are published. No other information regarding these patents is accessible, except at the cost of manuscript copies from the Patent Office. After 1847, the claims of United States patents are also published. From 1855, engravings (such as they are), illustrating specifications, are published, and later still, abstracts of patents appear in the Patent Office reports.

There were only thirteen United States patents referring to the decarburization of pig iron, issued by the United States prior to 1847. Of these, four were prior to the date reached in our former article (1836), and are mentioned below.

Such matter as is accessible, regarding the United States patents after these dates, will be compiled in chronological order, for the present series of articles.

STEEL FROM PIG IRON.

LEONARD, ENOCH, Canton, Mass.—1812. January 16.

MALLEABLE IRON FROM PIG.

LEWIS, THOS. C., Pittsburg, Pa.—1830. October 1.

PUDDLING AND HEATING IRON.

JONES, WM., Haverstraw, N. Y.—1833. December 16.

PRESSING OUT PUDDLE-BALLS INSTEAD OF HAMMERING THEM.

JONES, WM., Haverstraw, N. Y.—1834. April 18.

PURIFYING CRUDE IRON IN THE FINERY AND IN THE PUDDLING FURNACE, BY MEANS OF DEFINITE PROPORTIONS OF CHLORIDE OF MANGANESE, BICHLORIDE OF CALCIUM AND CHARCOAL.

DUCLOS, EDWARD FRANCIS JOSEPH.—1837. October 20. No. 7,448.

Manufacturing iron. The invention consists in combining with "cast iron and its scoria, while they are in a state of fusion," metallic chlorides (as of manganese and calcium), whose bases combine with the iron and slag, while the chlorine combines with the volatile impurities, such as sulphur, given off by the iron. Both of these combinations are said to produce a beneficial effect upon the iron, and produce an alloy equal to malleable charcoal iron. The specification and drawings describe a refinery furnace having a crucible. About 30 cwt. of cast iron are introduced into the furnace when it is at a white heat, and immediately afterwards 336 lbs. of dry chloride of manganese, and 6¾ lbs. of bichloride of calcium or "bleaching powder," are put into the crucible. Over the mixture is put a layer of wood charcoal two or three inches thick, and over that a layer of scoria, of like thickness, mixed with sufficient quicklime to combine with the free silica contained in the scoria. The whole is then melted, and the surface of the metal is again covered with wood charcoal. "The usual tools for working the metal are then introduced," and during the working portions weighing ten pounds each of the chloride of manganese and bichloride of calcium, are thrown in at intervals. The surface is to be kept covered with charcoal, and in half an hour the refined metal may be run out. It is then puddled, and during that process the chlorides must be added at intervals, in proportions of about one per cent of the weight of the metal. The bridge of the puddling furnace is made double, and the space between is filled up with charcoal. When the slag has been run out, and the metal brought to nature, in order to free it from all silicious impurities, it is submitted to the action of a charcoal fire.

[Printed, 5d. See "London Journal" (Newton's), vol. 12 (conjoined series), p. 345.]

ORE AND LIME SUBSTITUTED FOR HAMMER SLAG IN PUDDLING—REFRACTORY STONE USED FOR PUDDLING FURNACE BOTTOMS.

GOSSAGE, WILLIAM.—1838. June 18 No. 7,693.

Manufacturing iron. A cheap material is used as a substitute for "hammer slag" in puddling pig or crude iron. Argillaceous ironstones calcined and powdered small are introduced into the puddling furnace with the pig iron, either alone or mixed with powdered lime, quicklime, or carbonate of lime. The proportions required vary according to the qualities of the ores; about 450 lb. of pig iron, 30 lb. of calcined iron ore, and five pounds of slaked lime, are beneficial proportions. If the cinder does not separate easily, more lime should be used, and if the metal does not sufficiently "boil up," more powdered ironstone should be added. Also, instead of cast iron for the bottoms or soles of puddling furnaces, grit stones or other fire-resisting stones slightly hollowed to receive the charge, are preferred and claimed.

[Printed, 4d. See "London Journal" (Newton's). vol. 15 (conjoined series), p. 445; vol. 17, p. 329; also Patent No. 6,908.]

FURNACE—REFINING IRON.

SHARP, JAMES, Liverpool, Pa.—1838. June 23. (U. S.)

NOTE.—*No specification published.*

USE OF TAP CINDER IN PUDDLING.

BRADLEY, RICHARD; BARROWS, WILLIAM; HALL, JOSEPH.—1838. August 21. No. 7,778.

Making iron. The invention consists in the use of "tap cinder" obtained from puddling crude iron, instead of the cinder obtained from puddling refined iron, as a protection for the bottoms and sides of puddling furnaces. Tap cinder is a cheaper substitute. It is prepared by breaking it in pieces about six inches in diameter, and roasting it gradually for about eight days in a kiln like a brick-kiln, which is fully described in the specification and drawings.

[Printed, 9d. See "Repertory of Arts," vol. 11 (new series), p. 149; and "London Journal" (Newton's), vol. 21 (conjoined series), p. 343.]

PRODUCING PURE CARBURET OF IRON — DECARBURIZING BY MALLEABLE IRON OR METALLIC OXIDES, SUCH AS CHROME OR IRON ORE—USING OXIDE OF MANGANESE IN PUDDLING—USING CARBURET OF MANGANESE IN MAKING CAST STEEL.

HEATH, JOSIAH MARSHALL.—1839. April 5. No. 8,021.

"Improvements in the manufacture of iron and steel." The specification describes and claims the invention under four heads.

1st. The extraction from "pure native oxides and carbonates of iron" of pure cast iron, without the intervention of flux or the production of cinder.

2d. Formation of cast steel by fusing the said pure cast iron with malleable iron or metallic oxides, in such proportions as to decarburate the iron to a certain degree, and by completing the decarburation in a suitable cementing furnace.

3d. The use of a certain portion of oxide of manganese in the process of converting cast iron into malleable iron by puddling.

4th. The employment of carburet of manganese in preparing an improved cast steel.

Under the first head the operation of producing pure cast iron is described. A blast furnace is filled with coke, charcoal or other equivalent fuel, and thoroughly ignited. The furnace is then first charged with twenty pounds of the pure ore to 100 pounds of fuel. Other charges are added at intervals, and the proportions of the ore are gradually increased at every charge, until they amount to 65 or 70 pounds of ore to 100 pounds of fuel. The ore is to be broken small to the size of peas, and will produce about 50 pounds of pure pig iron for every 100 pounds of fuel. The metal should be run into iron moulds. The metal produced is pure carburet of iron. This is converted into steel of any requisite hardness, by melting it in a cupola, with coke free from sulphur, or wood charcoal, using no more fuel than will just melt the iron, and burn away the carbon it contains to a considerable degree. The carbon is further "neutralized or removed" by adding scraps of metallic iron, or oxides of iron or of manganese. "taking care not to decarburate the metal to such a degree as to render it infusible, but to leave about as much carbon as exists in cast steel." To produce a superior cast steel "sesquioxide of manganese or peroxide, which had been previously ignited," should be employed. Sometimes oxides of chrome or iron are used. The steely metal so produced is run out into cast iron molds, and the ingots are "converted into steel of any requisite degree of mildness, by a further process of decarburation," by cementing it with peroxides of iron, or of manganese without charcoal in a cementing furnace, the period to which the metal is subjected to the heat being proportional to the degree of mildness required. The quality of malleable iron is improved by introducing from one to five per cent of pure oxide of manganese into the puddling furnace with the iron without mixing any other substance with it.

4thly. An improved quality of cast steel is formed "by introducing into the crucible bars of common blistered steel broken, as usual, into fragments, or mixtures of cast and malleable iron, or malleable iron and carbonaecous matter, along with from one to three per cent of their weight of carburet of manganese," and melting the charge, and pouring it into molds in the usual manner.

[Printed, 4d. The duration of the patent was prolonged, by an application to the Privy Council, for seven years. See for an account of the application for prolongation, and for reports of the ten various legal proceedings, Webster's P. C., vol. 2, p. 213 et seq. See also "Repertory of Arts," vol. 16 (new series), p. 104; "London Journal" (Newton's), vol. 15 (conjoined series), p. 221; also vols. 24, 26; "Mechanics' Magazine," vol. 39, p. 368; vols 42, 58; and other publications relating to patents and legal reports. See Patents Nos. 2,363, 3.697, 4,397, 6,837, 7,448, 7,762.]

NOTE.—*This is one of the most notable patents on record. The great value of using manganese in crucible steel making, which enabled British steel-makers to compete with foreigners and to use British irons to a certain extent, was here first pointed out by Mushet. But the British steelmakers managed, after many hard legal fights, to use manganese in a manner not strictly infringing Mushet's patent, and thus to rob him of all share in the profits that really grew out of his invention. This department of the patent will be considered in another series of articles. The compiler of the abstracts of the British specifications says: "This patent has been the subject of ten legal judgments, and been contested in every superior court in Great Britain. The most important feature of the invention lay in the discovery, by Mr. Heath, of a method of employing oxide of manganese in the manufacture of iron and steel beneficially, and with the certainty of controlling its powerful pernicious properties by the counteracting influence of carbon exposed to it in the requisite proportions."*

The features of the invention relating to the decarburization of iron, are the use of malleable iron scrap and the ores of iron, chromium and manganese. Employing malleable scrap for this purpose was specified by John Wood, in 1761 *(see Van Nostrand's Magazine, No.* 3, *p.* 194). *The use of ore in puddling was more fully specified by Mushet, in* 1835 *(see Van Nostrand's Magazine, No.* 4, *p.* 361). *The present patent refers to the use of these substances in a cupola, for the production of a sort of decarburized pig iron to be further decarburized into steel.*

The employment of chrome is first specified in this patent. Its function here is obviously that of a flux.

THE USE OF STEAM IN THE FINERY OR PUDDLING FURNACE.

GUEST, Sir JOHN JOSIAH, and EVANS, THOMAS.—1840. May 28. No. 8,518.

"Improvements in manufacturing iron," &c. The invention consists in introducing steam into the refinery or puddling furnace, "forced upon, or into, or in contact with the metal. Any suitable means may be employed. The specification and drawings describe furnaces having telescopic injection tubes.

[Printed, 9d. See "Repertory of Arts," vol. 16 (new series), p. 281; "London Journal" (Newton's), vol. 21 (conjoined series), p. 447; "Mechanics' Magazine," vol. 33, p. 381; "Inventors' Advocate," vol. 3, p. 23; and "Engineers and Architects' Journal," vol 3, p. 396.]

NOTE.—*This is the first mention of the use of steam in connection with the purification of iron.*

PUDDLING FURNACE — PUDDLING WITH ANTHRACITE COAL.

COOPER, THOS., New York.—1840. Aug. 25. Reissued.—1841. March 18. (U. S.)

NOTE.—*No specification published.*

THE FINERY AND PUDDLING FURNACE CONNECTED, SO AS TO RUN LIQUID METAL FROM THE FORMER INTO THE LATTER.

BOOKER, THOMAS.—1841. Feb. 22. No. 8,855.

"Improvements in the manufacture of iron." These consist in making a connection between the finery and the puddling furnaces, which may be of any suitable construction so that "the heated metal from the refinery furnace" may be run or passed into the puddling furnace, without being first permitted to cool.

[Printed, 9d. See "Repertory of Arts," vol. 17 (new series), p. 27; "London Journal" (Newton's), vol. 21 (conjoined series), p. 107; "Mechanics' Magazine," vol. 35, p. 208; "Inventors' Advocate," vol. 5, p. 134; "Transactions of Society of Arts," vol. 54, p. 25; and "Engineers and Architects' Journal," vol. 7, p. 76.]

THE FINERY AND BOILING PROCESSES AT ONE OPERATION.

POWELL, LANCELOT, and ELLIS, ROBERT.—1841. April 24. No. 8,935.

"Improvements in manufacturing iron." The construction and operations of the refining, puddling and boiling furnaces are described as known before the date of the patent. The improved process consists in bringing iron, while in a molten state, from the blast furnace direct to the boiling furnace, and there subjecting it to the action of streams of blast or atmospheric air directed upon the metal while the boiling process is going forward. With a charge of four and a half hundredweight of iron (from Welsh ores) a stream of air introduced through "a pipe of one inch diameter, with a pressure of one and a half to two pounds on the square inch, leads to a beneficial result."

[Printed, 4d. See "London Journal" (Newton's), vol. 21 (conjoined series), p. 33; "Mechanics' Magazine," vol. 35, p. 366; and "Inventors' Advocate," vol. 5, p. 277; Patent No. 1,370.]

PIG IRON SOAKED IN WATER—MELTED IRON RUN INTO WATER, TO WHITEN AND PURIFY IT.

GREGORY, JAMES, and GREEN, WILLIAM.—1841. May 14. No. 8,959.

"Improvements in the manufacture of iron and steel." These consist in submitting the crude pig iron to the action of water. The iron, in the form of pigs, or broken small, is immersed in water, and allowed to remain exposed to its action "until there is no longer any change produced upon it; a period of from two to three weeks is generally sufficient for this purpose. The appearance of an oily looking scum on the surface of the water indicates that the water has produced its full effect upon the iron." Running water may be used, but standing water is preferred, as its scum indicates when the operation is completed. This process "causes the iron to become softer and tougher." If the iron is required to be of "close texture of that kind called brittle iron," it is to be heated to a bright red heat, and submitted to the action of cold water by sprinkling or immersion. If the iron be of impure quality it is fused in a "finery." Iron so treated is superior for casting and for conversion into wrought iron. The improved process for refining, which may be used alone, or in conjunction with that just described, is as follows: The iron is melted "in a reverberatory or other suitable furnace," and then poured, "while in its melted state, through a vessel, the bottom of which is perforated with holes about one-quarter inch in diameter, lined with clay. The fused metal is received in a vessel of cold water," of any size; by preference it should be so deep "that the drops of metal may be well cooled." Iron is considerably refined by this operation; it "possesses a close texture, and is of a white color," and is "much better adapted for conversion into steel than the iron manufactured in the ordinary method."

[Printed, 3d. See "London Journal" (Newton's), vol. 21 (conjoined series), p. 34; "Mechanics' Magazine," vol. 35, p. 413; and "Inventors' Advocate," vol. 5, p. 324 See Patents, Nos. 759, 4,151.]

BRIDGE CONSTRUCTION.

The principles and practice in modern iron bridge construction are thus mentioned in "Engineering": Little that is new in principle has been achieved during the last year. Wrought iron arches, where arches are employed at all, are certainly coming into increasing favor. The widest wrought iron arch yet constructed is that of the Pont d'Arcole, in Paris, 262 ft. in clear span. A somewhat later example was that of the bridge over the Thiess, at Szegedin, in Hungary, and Mr. Fowler was the first to adopt wrought iron arches in England, viz., in his fine railway bridge, of four 175 ft. spans, across the Thames, at Pimlico. Mr. Fowler has attempted, experimentally, with great success, to construct a large concrete arch, with a view to the application of the system in his practice. On the Continent concrete voussoirs are sometimes employed, and the attainment of a monolithic arched bridge, of considerable span, is not beyond the resisting powers of the material.

Engineers should examine fully into Mr. Sedley's proposed system of double cantilevers with an arched or trussed span placed between them. It secures a very considerable economy of material in long spans. Mr. Sedley not long since tendered for the construction of the great Moerdyk bridge, which he proposed to complete in eleven spans of 400 ft. each, on an estimate of between £600,000 and £700,000.

It is desirable also to inquire if more than one tension member is necessary in trussed bridges carrying their load on the level of the upper booms. We last week illustrated a Norwegian bridge of triangular section, only one tension member being provided for the two booms in compression. So, too, the great (455 ft.) spans of the Saltash bridge have each but one compression member, and we may note that in his design for the Kentucky railway suspension bridge, of 1,224 ft. clear span, Mr. Roebling proposed to employ a single stiffening girder of timber beneath the roadway.

When rolled rings, requiring no riveting, are once produced upon a commercial scale, it is probable that engineers will introduce new forms of compression members in all trussed structures, the circular strut being far stiffer for a given weight of iron than the cruciform section obtained by riveting up T or angle iron.

There is a greater tendency towards pin jointing in trussed girders, as distinguished from the clumsy mode of riveting the parts together. Warren's girders have always been made with turned pin joints, as are the joints of all chain suspension bridges, and Mr. Hawkshaw has employed turned pins instead of rivets to a very considerable extent, as in his Charing Cross and Londonderry bridges. In America, Fink's, Bollman's, and the Murphy-Whipple iron bridges are all made with turned pins.

But, after all, there is less to be said of the structure than of the appearance of our bridges. When shall we have engineering science wedded to true architecture, as in the case of Mr. Page's fine bridges, and in those, worthy a superior age, constructed by Mr. Joseph Mitchell upon the line of the Highland Railway? The latter, taking their abutments and piers along with their girders, are the finest railway bridges ever constructed, except with arches. Too many, far too many, of our engineers take a pride in ugliness, and perpetrate it wilfully. The time will come when offended taste will cry out and demand the demolition of their ugly works, and we shall not be surprised if the time is soon. Bridge work should no longer be all calculation and contract, but be redeemed by the graces which refined minds are always so ready to lavish upon structures of far less publicity and importance.

THE "ROUND OAK" COAL AND IRON WORKS.

Mr. Samuel Griffiths, in the "Birmingham Daily Gazette."

The Earl of Dudley's iron works at Round Oak are situated on the high road between Dudley and Brierly Hill, and are, without doubt, the most complete in South Staffordshire, regularly turning out a quality of iron unrivalled by, if not superior to, the production of any works in the Black Country. We arrive at this great establishment by the West Midland division of the Great Western Railway, which runs parallel with one angle of the works. A canal connects it with the North-Western Railway, and 12 locomotive engines are employed to serve these works, thereby rendering assistance also over 40 miles of railway, which traverse his lordship's collieries. The works, together with the offices, etc., cover 30 acres of land, and they are capable of turning out from 500 to 550 tons of best finished iron per week. There are nine steam engines in the mills and forges, all working vertically or horizontally, and a very large steam hammer, with the last improvements, which is capable alike of dropping a 20-ton blow or cracking a nut without bursting the kernel. Here they have four large forge hammers or helves, and this is the only method adopted to form the puddled balls into blooms or slabs, as they may be required. Old fashioned shingling is the practice here; neither squeezers nor patent shingling of any kind is resorted to.

There are five rolling mills—one 16 in. plate mill, a 12 in. ditto, an 8 in. and 7 in. bar mill, with a good hoop mill; and the space allotted to the hoop mill and the fencing wire mill—indeed, all the mills in these works—is admirable for its extent and convenience. The speeds are higher than anything in South Staffordshire, and the machinery, by its quiet and steady motion, forcibly reminds one of the regularity of clock-work. We have no hesitation in saying that the construction and perfection of the gear which drives all the mills and forges supersedes anything we have seen in this or any other country. The wheels, when in full work, make very little noise; the driving wheels are large, and as the engines run fast, the nut on the fly shaft of necessity is very rapid, but the sound resembles the gentle murmur of the crabwood gearing of a flour mill rather than the unremitting contact of metal with metal in their constant revolutions. We hear no banging sounds like a sledge hammer on the cog of a wheel, which are generally heard in the iron works of the Black Country. We were much struck with the truth of all the driving wheels; indeed, the general lines of the work reminded us of a parallel, always square and rightly placed. We could not help observing the scientific distribution of metal in the numerous wheels and shafts. Even those unwieldy blocks of metal called cam-rings were shaped with a view to a scientific distribution of the iron, and the engineer, while exercising economy in this respect, had not forgotten the ornate. There are 53 puddling furnaces, nine ball furnaces and two heating furnaces. The fettling used is ground bull-dog only. Neither pottery-mine nor hematite ore is permitted in the works.

The bull-dog is calcined exclusively from the taps of the puddling furnaces on the spot. The puddling furnaces are fixed at equi-distance from the hammers, and as the interior area is completely laid with square plates, the roofing being sustained by a very high wall plating on columns all round, the works present a clean and comfortable aspect, and must be comparatively cool in summer time, which is a great desideratum. A railway serves the coal and removes the ashes from the back, while a second railway deposits the pig-iron and ground bull-dog on the standings at the front of the furnaces. The kilns for calcining bull-dog are fixed at equi-distance between both works, and a railway takes the taps from the works to the kilns, returning loaded with the ground fettling for the puddling furnaces, which struck the writer as a very perfect and economic arrangement for this otherwise dirty and expensive process. The last erections here are the new forges, situated a few hundred yards from the old mills, containing 28 puddling furnaces, fixed round the works in the shape of a horse-shoe, being ministered to by two large forge hammers, which are driven by two vertical engines 55-horse power each, each engine driving a hammer, forge rolls, &c., *per se*, so that the motive power of the one is disconnected with, and independent of, the other; the engines, driving wheels, rolls, &c., being fixed parallel with the heels of the horse-shoe figure of the forges, a space is left between the driving wheels, and the engines being fixed underground, but everything as firm as a solid rock. The puddling furnaces are served with coal, metal, &c., by rail, back and front, as described above, and the puddled bars, billets, &c., are removed by rail, with locomotives, into the mills, which are at some little distance, for consumption.

It must be observed that the whole of the pig-iron or plate-iron consumed is made from the Earl of Dudley's mines, raised on the estate, and smelted at his own blast furnaces. Nothing is used but his lordship's ten-yard coal, which is doubtless the best in the world for the manufacture of iron. No foreign pigs of any kind are permitted in the works, hence the famous quality of the iron produced. These great works are justly famed for the manufacture of large rounds and squares. Rounds are rolled here as high as six and a half inches diameter down to seven-wire gauge; and the higher sizes of rounds are in general request at the machine shops of the kingdom for piston rods, owing to the compactness and superior quality of the iron rolled here. Boiler plates are made with facility, of large size, up to 18 cwt.; angle bars and T-iron of great length are made, from 6 in. by 6 in. to $\frac{3}{4}$ in. by $\frac{3}{4}$ in. flats of all thicknesses, from 12 in. down to $\frac{1}{2}$ in. wide; an unequal size of angle iron, from 8 in. by $2\frac{1}{2}$ in. down to 2 in. by 1 in.; likewise channel iron, from $3\frac{1}{4}$ in. to $\frac{3}{4}$ in.; glan iron, ovals, round-edged flats, core bar iron, bevel iron; Z-iron, or, in other words, double-angle iron; square-edged and feather-edged iron, boat-guard iron, shutter iron, great bar iron, with various other specialities too numerous to mention. Here likewise the famous U-iron is produced, which up to this time has not been rolled at any other works in England. Rails of a very superior quality are likewise manufactured here, for the rolling of which the works offer great facilities. A layer of steel is welded on the top of the rail, the web or foot being made of his lordship's best fibrous iron, which is said to give greater strength and durability to the rail than the steel rail made in other districts.

The Earl of Dudley's iron stands quite at the top of the Staffordshire makes, and possesses all those peculiar qualities which have rendered Staffordshire iron so famous throughout the world in a more eminent degree than any other maker. This mainly arises from two causes—first, the splendid ten-yard coal, so abundant in his lordship's estates; and, secondly, the superiority of the earl's argillaceous iron-stones found west of Dudley. The iron produced here is consumed by shovel and spade makers (in plating bars), for horse-shoes, rivet-iron, cotton rollers, gun barrels, bayonet iron, saddlers' iron-mongery, for wire-drawing purposes, locomotive engines, and agricultural machinists' purposes. Its tension while hot in punching is marvellous. It is likewise used for all bright work, easily polishing without specks, and for other specialities, which renders its adoption desirable where it can be obtained.

The Earl of Dudley's finished iron is largely consumed at the great engine shops on the banks of the Neva, in Russia, and is sent to Canton, Foo-chow-foo, and Pekin, in China; to Hokudadi and Yokohoma, in Japan; Cabul and Candahar, in Affghanistan; and even the almost unexplored regions of Thibet are supplied, via Cashmere, with some particular kinds of iron from these famous works; and pig-iron with his lordship's brand was found in Theodore's cannon foundry in Abyssinia, which must have been carried for some hundreds of miles on the backs of the attenuated mules of that country. The superiority of this marvellous iron is owing, no doubt, to three or four circumstances. In the first place, all other makers buy different mixtures of pig-iron. The Earl of Dudley makes at his blast furnace establishment the best iron that can be made out of the materials raised in his own estates, and consumes these pigs, and no others, at the Round Oak Works.

The Round Oak Works were founded by the late Mr. Richard Smith, who for thirty years was faithfully and successfully engaged in developing his lordship's coal and mineral empire. The tact, talent, and business abilities of the late lamented Mr. Smith were well known and appreciated in the iron trade. Mr. Frederick Smith, the present manager, is a gentleman and a scholar, a Fellow of St. John's, Oxford, but obtained immense practical knowledge under the guidance of his late father; and as he inherits the business qualities of his father, the efficiency of the management continues unabated. Probably a greater willingness is evinced to adopt all modern improvements and adapt these great manufacturing operations to the requirements of the day, keeping abreast in all departments with the rapid progress of the iron age in which we live.

NAVAL ENGINEERING.—At the late meeting of the Institution of Naval Architects, many important papers were read, abstracts of which will appear in these pages.

HYDROGEN AS AN ILLUMINATING GAS.

From the "Mechanics' Magazine."

In every process, chemical or mechanical, a certain amount of loss or waste of either material or power must take place. The results obtained by a chemical process never coincide exactly with the theoretical formula, nor, mechanically, can the work done ever equal the power applied. An ignorance, or, what is worse, a culpable neglect of these fundamental principles, has led scientific fanatics to spend their time, money, and ultimately their lives, in a fruitless search after the impossible. The loss accruing to ordinary gas, from the very commencement of its manufacture, to the moment that it flows from the burners, as a source of illumination, is occasioned by both chemical and mechanical unavoidable imperfections. The latter is caused by leakage, owing chiefly to defective joints, unsound pipes and the carelessness of those who are concerned in its manipulation and distribution. The former is due to chemical action solely, and could scarcely be prevented, which is not the case with the other sources of loss. About fourteen per cent may be taken as the average loss incurred in the manufacture and burning of ordinary gas, or that which represents the actual discrepancy between the theoretical and practical results. The composition of ordinary gas consists mainly of carbureted hydrogen gases; and as hydrogen itself possesses no power whatever of illumination or brilliancy, it is not, at first sight, quite obvious what advantage results from its presence. Any-one who has dabbled in elementary chemistry is aware that hydrogen gas, when tolerably pure, burns with a pale blue flame, emitting little or no light, but endowed with a very high temperature. At the same time, by causing its high temperature to act upon other bodies, such as platinum and lime, it develops a flame of great beauty and brilliancy. To a similar cause is due the illuminating properties of ordinary gas. The action of the high temperature of the burning hydrogen upon infinitesimal particles of carbon renders them incandescent, and imparts to the gas its powers of illumination. Hydrogen, therefore, destitute of brilliancy when pure, becomes possessed of that property when in mechanical combination with carbon—in other words, when it is carbureted. If it were possible to bestow upon hydrogen illuminating properties without carbureting it, as in the ordinary manufacture, the whole process would be rendered much simpler and more economical.

It has been asserted that it would be found a great advantage to employ a much larger proportion of hydrogen in the ordinary gas than what at present prevails; in fact, to constitute it rather a hydrogen gas than that of which it is now composed. A very large proportion of hydrogen is lost in the manufacturing process, which might be easily preserved and utilized, resulting in the production of a gas of a superior quality. The same may be stated with respect to other volatile and illuminating ingredients, including the paraffin and benzine, which, for the most part, are left in the bye products. Were hydrogen more carefully sought for and preserved in the manufacture of gas, the volume would be considerably increased, in addition to a greater purity being imparted to the product. It is notorious that the ordinary gas, in many of the smaller towns, is so impure, and possessed of so small an il uminating power, that many persons refuse to have it laid on to their premises. A gas composed mainly of hydrogen would be free from most of the noxious and disagreeable properties unquestionably possessed by our present great source of public illumination, but until it can be demonstrated that a better gas can be supplied at the same rate, we shall, as usual in such matters, stick to the old plan of manufacture.

IMPROVEMENT IN PUDDLING.

FINE ORE STIRRED IN WITH THE CHARGE.

The remarkable results of the Ellerhausen process—mixing 30 to 33⅓ per cent of fine ore with pig iron, previous to its treatment in the puddling furnace, has led to a number of experiments in a similar direction. One of the most important of these experiments was recently made at the works of Messrs. Henry Burden & Sons, Troy, and consisted in melting the pig iron in a puddling furnace fettled with about half the usual quantity of lump ore, scattering over the iron and stirring into it 30 per cent of fine ore, lowering the heat slightly to give the iron and ore time for reaction, and then raising the heat and balling the charge in the usual manner, but with a saving of some 30 per cent in time and an improvement in quality of product. This treatment was clearly pointed out, in kind, but not in degree, by David Mushet, 34 years ago.* The results given below were furnished by Messrs. Burden for the public benefit, and were ascertained with great care and accuracy.

Record of Experiment at Nos. 10 *and* 12 *Single Puddling Furnaces, "Burden Iron Works," week ending* 20*th Feb.*, 1869, *charging* 448 *lbs. of Pig Iron to each heat, and using* 30 *per cent. Fine Ore.*

SUMMARY OF RESULTS.

Old System Puddling.	*New System Puddling.*
Coal consumed per ton of puddled bars ....2,698 lbs.	Coal consumed per ton of puddled bars ....2,213 lbs.
Fettling ore consumed per ton of puddled bars ......1,374.	Fettling ore consumed per ton of puddled bars.....682 lbs.
Average turn six heats, 2,667 lbs.	Fine ore consumed per ton of puddled bars.......646 lbs.
No waste.	Av. turn eight heats, 3,552 lbs.

Saving by new system in coal per ton of puddled bars over old system.. 485 lbs.

Increase in consumption of ore per ton of puddled bars over old system........................ 46 lbs.

Increase in product of puddling furnace over old system.. 34 per cent.

Gain in yield of both furnaces over old system during the week........................ 2,512 lbs.

LIGHT RAILWAYS.—Mr. Zerah Colburn is preparing a very comprehensive paper on this subject, to be read before the Institution of Civil Engineers.

* See Van Nostrand's Magazine, No. 4, page 361.

IRON AND STEEL NOTES.

STRENGTH OF STEEL VARIOUSLY CARBURIZED.—The following tables are from a list of experiments made by Mr. Thomas E. Vickers, of Sheffield:

Softest, or least carbonized steel containing .33 per cent carbon, marked No. 2. The hardest, or most highly carbonized, containing 1.25 per cent carbon, No. 20; the intermediate numbers representing intermediate degrees of carbonization.

TENSILE STRENGTH.

Description of steel.	Proportion of carbon. (Approxi.)	Breaking strain per square in.	Elongation.	Specific gravity.
No.	Per ct.	Tons.	Inches.	
2	0.33	3.4	1.37	7.871
4	0.43	34.0	1.37	7.867
5	0.48	37.5	1.25	7.855
6	0.53	42.5	1.12	7.855
7	0.58	41.5	0.81	7.852
8	0 63	45.0	1.00	7.848
10	0.74	45.5	0.69	7.847
12	0.84	55.0	1.12	7.840
15	1.00	60.0	1.00	7.836
20	1.25	69.0	0.63	7.823

Tensile strength is increased by the addition of carbon until the steel contains 1.25 per cent, when it sustains about 69 tons per square inch; beyond this degree of carbonization the steel becomes weaker, until it reaches the form of cast iron.

Transverse Strength of Axles.—Axles turned to 3.94 inches diameter at center, 3.25 at the ends, placed on bearings three feet apart; ram weighed 1,547 lbs.; dropped on center of axle from height of one foot, increasing up to 36 feet fall.

Materlal of axle.	Proportion of carbon. (Approximate.)	Total number blows.	Height of fall in last blow.	No. of blows sustained from 36 feet high.	Sum of deflection.

CONSTRUCTION OF BLAST FURNACES.—An interesting and instructive experiment bearing upon the construction of blast furnaces, has recently been made at the "Consett Iron Works," at Durham, England. The Consett Iron Company smelt each year about 200,000 tons of ore in four blast furnaces. At present the waste gases are only taken from one furnace, on the bell and hopper system, but one of the furnaces is being altered so that the waste gases can be taken off on a modification of the side flue system, a little novel in character. The blast is heated just now to 1,000 degrees by a couple of ∩ cast-iron pipe stoves. These are to be removed, and four stoves on Whitwell's principle substituted, from which the best results are anticipated. Mr. Radcliffe, the superintendent, believes that the extraordinary results obtained from the high and large furnaces now popular in the Cleveland District are due not so much to the dimensions of the furnace as to the excessively high temperature of blast with which they are worked, and is inclined to the opinion that the proper capacity of furnaces has been overstepped, and cites the following interesting fact in support of his theory. Some time since it was decided that a new furnace should be erected at Consett, with a height of seventy feet.—It was built and worked for some time; but the yield per ton of coke and the quality of iron were both found to be inferior to the yield and quality from the other and smaller furnaces. The furnace worked on Cleveland and hematite ore with a very good and clean coke quite capable of carrying the burden. It was then determined to cut the furnace down to a height of fifty-five feet, and the result was eminently satisfactory; the yield and quality were greatly improved, and the furnace is now one of the very best in the district. The blast is supplied by two high-pressure engines of an old type, with six feet six inches blowing cylinder, nine feet stroke, and a supplementary engine, which also drives a pair of plate rolls. The waste gases are used to raise steam in a magnificent set of new boilers, six in number, each 70 feet long, egg-shaped, with a diameter of 3 feet 10 inches. They are set in a very peculiar way. Cast-iron columns are erected on the brick-work in which they are set, and on these are supported five cast iron girders running across the tier of boilers.

From these girders depend sling stays, which are secured to double angle iron semi-circular rings riveted to the upper side of the boilers. A straight flue, 70 feet long, runs the whole length of the boiler below, right to the stack. The stack in connection with these boilers is 250 feet high, and 24 feet diameter inside at the base.—*Bulletin Am. I. & S. Ass'n.*

PHOSPHORUS IN CAST-IRON.—While the question of phosphorus and its effects on iron is being discussed, the following method of examination employed by a French metallurgist, M. V. Tantin, deserves notice.

M. Tantin says: "It is well known that very small quantities of phosphorus produce no sensible alteration in the quality of cast iron, whereas if the proportion exceeds a few thousandth parts the iron is robbed of its most essential qualities. It is very important, therefore, to ascertain the exact amount of phosphorus present. Nearly all the methods in use for this purpose consist in treating the iron by means of oxidizing agents, so as to cause the phosphorus to pass into the condition of phosphoric acid, which is precipitated in the state of a magnesian compound.—Several causes of error exist in this treatment, for (1.) a part af the phosphorus escapes the action of the agents, and disengages itself in the form of an hydrogenous compound. (2.) It is necessary to act upon very diluted solutions to prevent the ammoniacal-magnesian phosphate mixing with the oxide of iron, in which case it is difficult to collect the small amount of phosphate deposited in the sides of the vessel in which the precipitate is made. (3.) The arsenic which may be contained in the iron enters into the magnesian precipitate in the form of arseniate as insoluble as the phosphate.

* Cracks began to show at 10 lb. blow, with 20 feet height of fall, and increased with each such subsequent blow.

† Two large cracks opened at five pound blow, and considered as broken.

"In order to avoid these objections, I tried to attain my object by a directly opposite road, that is to say, in disengaging the phosphorus in the form of an hydrogenous compound, but then arose the question whether the whole of the phosphorus passed into the form of a gaseous product. This was, however, proved by the fact that no trace of phosphorus was ever to be found in the residuum after the iron had been completely acted upon by hydrochloric acid. This result ought to cause no surprise, considering the very energetic affinity which phosphorus has for hydrogen. The phosphureted hydrogen produced by the action of hydrochloric acid on iron is almost always accompanied by sulphureted, arseniated, and carbonated hydrogen. In order to effect the separation of these gases, they may be made to pass first through a Wolf's bottle containing a solution of potash, which absorbs the sulphureted hydrogen; then through a solution of nitrate of silver, which transforms the arseniated hydrogen into arsenite of silver soluble in the liquid becomes slightly acid, while phosphureted hydrogen precipitates the argentine solution and forms insoluble phosphorus.—The phosphorus being thus absolutely separated from the sulphur and the arsenic, its amount is ascertained with the greatest ease; the phosphure of silver is treated with nitro-muriatic acid, and thus transformed into chlorure of silver and phosphoric acid, which is precipitated in the form of ammoniacal-magnesian phosphate. This precipitate, when calcined, gives the proportion of the phosphorus to the iron.

"In order to obtain the whole of the phosphorus the following precautions must be observed: Let the iron be attacked gradually, otherwise a portion of the phosphureted hydrogen may traverse the solution of nitrate of silver without being absorbed. And when the action on the iron is finished, pass through the apparatus a stream of hydrogen which has previously been washed in acetate of lead.

"The solution of potash contains all the sulphur which was present in the iron treated, and in order to ascertain the quantity of that substance the solution must be treated with acetate of lead; the precipitate produced is at first a mixture of oxide and sulphite of lead, but the oxide is soon redissolved and the sulphite still remains. The precipitate must be collected in a filter, washed with distilled water, and completely dried before being weighed."—*The Engineer.*

THE SIEMENS-MARTIN PROCESS.—The "Mining Journal" says that Mr. Bernard Samuelson, M. P., has erected extensive works at Newport and South Stockton, for the manufacture, on a very large scale, of rails, angles, plates and sheets, by this process. Richardson and Johnson's process of purification, will be used in the preliminary processes, and Siemens' furnaces for heating, &c., are to be employed throughout.

EXTENT OF THE BESSEMER MANUFACTURE ON THE CONTINENT.—There are now in use in Europe, Italy and Russia excepted, 128 Bessemer converters, these having a total capacity of 555 tons. Krupp is the largest owner of Bessemer converters, there being thirteen at the Essen works, some of them having a capacity of seven tons. In France 20,000 tons of Bessemer steel were made in 1867, and 35,000 tons in 1868.

WATER BOSHES FOR CUPALAS.—In the "Mechanic's Magazine" of February 12. 1869, this construction, as patented by Mr. John Thomas, of Newcastle-on-Tyne, is fully illustrated and described. The object is to prevent the excessive wear of bricks. The water boshes are covered on the inside with spikes, like a founder's loam plate, by which the refractory lining is held in place.

NEW METHOD OF PILING LARGE ARMOR PLATES.—An experiment in rolling large armor plates was recently made at the works of Sir John Brown & Co. The plate manufactured and finished is 12 ft. 8 in. long, 8 ft. 6 in. wide, and 5 in. thick. The difficulty experienced in producing large plates has hitherto been in heating sufficient wide piles in the furnace, and in thoroughly driving out the slag and cinder, which would become incorporated in the plate. By the process of Mr. Ellis, the managing director of the company, the piles are built up comparatively narrow, and are passed through the rolls until the length of the mass becomes equal to the finished breadth of the plate. The pile is then turned and rolled out in the direction of its breadth, until the required length and thickness is attained. The pile from which the plate was constructed was built up of five slabs, each 7 ft. by 6 ft., and 3¼ in. thick, weighing 14 tons, and was heated for sixteen hours previous to rolling, which operation occupied three-quarters of an hour from the time when the pile was withdrawn from the furnace. The successful issue of this experiment promises a great advance in the manufacture of large armor plates; and the difficulty of dealing with piles being avoided, plates 8 ft. wide, and not only 12 ft., but 20 ft. or 30 ft. long, can be produced by the method of Mr. Ellis.—*Engineering.*

CONTINENTAL COMPETITION WITH ENGLAND.—Belgium and France often obtain considerable orders from the Russian and Austrian railways. The plan adopted in Belgium is to form a committee of ironmasters, who appoint one of their number to tender for any large contracts that may be offered. He proceeds to the spot, and works for the interest of all the makers of rails in Belgium; the ironmasters decide upon the terms which he may offer, and the orders are divided among them pro rata of their means of production. Payment being very often made by bills or guarantees, which individual firms could not accept without danger, a financial association supports the operations of the committee; by these means the risk is divided amongst a large number of individuals, and when losses are made they are less heavy, from being divided. Our authority also has the following: The English railmakers formerly supplied the greater part of the steel rails required for the American railways; now the French houses seem to threaten formidable competition. MM. Petin-Gaudet et Cie. have, it is said, recently supplied 5,100 tons of steel rails to the New York Central Railway Company, and considerable quantities to other companies.—*Journal des Travaux Publics.*

BLAST FURNACE SLAG FOR BUILDING AND PAVING.—The following method is now adopted in several iron works in Belgium: The slag is allowed to run direct from the furnace into pits about eight or nine feet in diameter at the top, with sides sloping inwards towards the center, where they are about three feet deep. The mass is left for eight or nine days to cool, when a hard, campact, crystalline stone is obtained, which is quarried and used for building purposes, but chiefly for paving-stones. They appear to wear exceedingly well, being quite equal to the grits and sandstones already so much used.

EXPANSION OF IRON DURING COOLING.—It is stated in the "Scientific Review" that Mr. Gore, of Birmingham, whilst making some experiments on heating a strained iron wire to redness by means of a current of voltaic electricity, has observed that on disconnecting the battery, and allowing the wire to cool, during the process of cooling the wire suddenly elongated, and then gradually shortened until it became quite cold. No explanation of the action has, so far as we are aware, been advanced.

ORDNANCE AND NAVAL NOTES.

Krupp's New Eleven-Inch Guns for Russia.—About five years ago, when the Russian artillery made use of muzzle-loading rifled cannon, the Russian government had ordered of M. Krupp a cast-steel gun on that system, rifled 11-inch bore, English measure. Since then, numerous experiments having been considered to prove the superiority of breech-loading guns throwing projectiles larger than the bore, the Russian artillery has decided on adopting these guns exclusively. At the time of this decision the 11-inch was in a forward state of manufacture as a muzzle-loader, and when its conversion was contemplated, there was reason to fear that the walls of the gun would be too thin for the slot for the breech-piece; but further experiments on the resistance of breeches of different thicknesses having demonstrated the possibility, the alteration to a breech-loader on Krupp's principle was made. This gun has been subjected to a prolonged trial of 400 rounds, the number fixed by the Russian authorities. The details of the gun are:—Total length of bore, 160.2 English inches; length of rifling, 113 in.; number of grooves, 36; weight of gun, 25 tons, 11 cwt. 3q. 3 lb. The weight of the projectile is 496 lb.; the weight of the charge, 82½ lb. of Russian prismatic powder. The initial velocity communicated by this charge to this projectile was 1,308 ft. The gun stood the 400 rounds with this charge, and remained in a serviceable condition. The above quantities, as well as those which follow, are all in English measure, the equivalents having been reduced from the Prussian denominations.

The breech-piece was Krupp's single round wedge. Two were furnished for the experiments, one having a Rodman knife apparatus for measuring the pressure of the gas in the chamber, and which was only used for that purpose; the other an ordinary breech-piece intended for the endurance trial. This breech-piece, in this experimental practice, worked throughout with the greatest ease, and all escape of gas was perfectly prevented by one Broadwell ring, which sufficed for the whole number of rounds. The explosion of the charge took place in the direction of the axis of the bore, ignition having been effected by a vent through the breech-piece. The gun was sponged out after every 30 rounds, but care being always taken to lubricate the lead coatings of the projectiles there was not the slightest appearance of leading in the grooves. The gun was sponged with soapy water, which effectively removed the slightest fouling. The guttering formed at the seat of the projectile during the firing by the passage of the gas did not exceed three millimetres in depth at the finish of the trial, and all did not seemingly attain this depth. These channels are larger than those observed after 725 rounds in the Krupp breech-loading 9-inch gun, and this circumstance is attributed to the fact that the 11-inch gun had an ordinary chamber concentric with the bore; whereas all the guns of the new construction—such as the 9-inch gun referred to—have eccentric chambers. The 11-inch gun, having been a muzzle-loader, has not the necessary length of bore for a breech-loader, and the new breech-loading guns of this calibre about to be supplied from Krupp's works will have the bore longer by 2½ calibres, so that the initial velocity communicated to the 496-pounder shot by a charge of 82½ lb. of prismatic powder will be increased to about 1,360 ft. per second. The gun was discharged, as we have said, by a vent through the wedge; but there was another vent on the top of the gun, which was closed by a steel screw, and was not used. The objects of the experiments were to ascertain the charge required to give a shot 550 lb. Russian (496 lb. English) an initial velocity of at least 1,300 ft.; to demonstrate by a trial of endurance that, with the chargo thus arrived at, a Krupp 11-inch breech-loader will stand a greater number of rounds than is required to render it fit for active military service.

With respect to the powder, experiments in Russia and at Essen had shown that the prismatic powder introduced into Russia some years since was very well adapted for attaining a high initial velocity without an excessive strain on the gun, and the Russian government, therefore, sent to Krupp's factory a quantity of this power, manufactured in 1865 at Ochta, for these trials. The factory had also a stock of prismatic powder made by Ritter, of Hamm, in Rhenish Prussia, according to the Russian formula. The cartridge bags were of single cotton stuff, the cartridge forming a regular hexagon, with tiers of 37 prisms; the greatest diameter of the hexagon being 9.65 in., the smallest 8.80 in.; the length of the cartridge without the choke, 27 in. The shot were of solid cast iron, with lead coating. The gun was mounted on a proving carriage with cast-iron sides, which afforded no convenience for loading; the recoil was on an inclined plane, so that the gun, after each round, ran back to nearly its original position. It stood in a roofed place, and the firing was into an earth butt at a distance of about 62½ ft., also roofed over. The initial velocity was taken with Captain Le Boulange's chronograph; the first wire target stood at 18 ft. from the muzzle; the second was 32.9 feet from the first. The target wires were fastened separately to iron frames; their thickness three-eighths of an inch in the front, and a quarter of an inch on the second target; the insulated communicating wires were perfectly protected from the gas when the gun was fired. The average pressure of the gas of 3,209 atmospheres is stated to be far from straining the gun up to its limit of elasticity. Ritter's powder, according to the details of the experiments, appears to try the gun less than the Russian powder. The piece was served by eight men, two of whom had to fetch the cartridges from a magazine 150 metres away. For the sake of the durability of the earth butt the shot were dug out after every 60 or 70 rounds. Between every two days consecutive firing gutta-percha impressions were taken and the chamber measured. The gutterings have not, even after 400 rounds, assumed a character in any way serious to the durability of the gun. The regular breech-piece did duty in the gun during 307 rounds, with a charge of 91 Russian lbs. (82½ lbs. English).

Putting together, for comparison, the results of the trials with Krupp's 9-in. 12-ton gun, with hoops, tried in Russia, his 11-inch gun (26 tons), with hoops (trial at Essen), and our English 12-inch muzzle-loader (trials in England), we have the *vis viva* of the shot in metre tons as follows:

Gun.	Caliber.	Charge.	Shot.	Initial Velocity.	Vis viva. Meter Tons.	Vis viva per Centimeter. of Circumference. Meter Tons.
	in.	lb.	lb.	ft.		
Krupp's b l. 15 tons.	9	46	275	1,340	1060·5	15
Krupp's b.l 26 tons.	11	82½	475	1,353	1975·0	23
English m.l. 24 tons.	12	79	600	1,180	1796·7	19

According to the above formula, Krupp's 26-ton 11-inch breech-loader is a more powerful gun than our 12-inch 24-ton muzzle-loader. The new guns, now making under the Russian contract, will be of rather larger measurements than the converted gun used in the experiments above described. Their details will be: Weight, including breech-piece, 25 tons 11 cwt. 3 qr. 3 lb.; no preponderance at the breech; length over all, 18 ft. 4 in.; rifling—36 grooves, 0.135 in. deep, 0.76 to 0.64 in. wide; width of lands, at chamber, 0.17 in.; of grooves, 0.79 in.; at muzzle, 0.17 in. and 0.32 in.; diameter of bore over the lands, 11 in., over the grooves, 11.40 in.; weight of steel shell loaded, 496 lb.; charge for gun, 82 lb.; initial velocity of projectile, 1,360 ft.—*London Standard.*

STEAM LAUNCHES.—One of the most important parts of the equipment of a ship of war is undoubtedly her boats and their capabilities. In this respect the ships of the English navy, a few years since, were far behind those of France or Russia; but at the present time they are much more efficiently provided than the ships of any other nation. For some time after steam-power was applied for the propulsion of boats attached to ships of the French and Russian navies, our own authorities stood by oars and sails, and when they did follow on the new track it was only done at first in a compromising and bungling kind of way. In their application of steam-power to boats our friends aimed at rendering the boat a kind of miniature despatch tender to the ship, possessing as much speed as could be given by the engine and boiler carrying power of her tonnage, without the usual heavy gun at the bow or stern, and with no great capacity for stowage beyond fuel, but with good towing powers, so that she could take a string of heavily-armed boats into or out of any position that might be desired on a coast at a moderate speed. Our first efforts in the same direction was to place twin-screw engines and boilers in the heavy built steam-launches already attached to our ships, retaining them at the same time in all their original form as gun-carrying boats, with armed crews and stores of shot, shell, masts, sails, oars, water, and provisions, &c.; the clumsy bluff-bowed monsters being, when thus loaded, scarcely able to hold their way against a moderate wind or tide in a river way, and useless altogether for towing purposes.

The fitting out of two surveying-sloops for service in the Chinese and Japanese seas led to the introduction of quite a different class of steamboat into our navy, a type of boat which more nearly approached that adopted in the French and Russian navies in its general principles as simply a despatch and towing-boat, but excelling them greatly in having superior speeds combined with the life-boat principle in the boat's construction, the latter arrangement rendering them unsinkable when filled with water to the gunwale's edge when carrying engine and boiler and a double crew on board. Quite recently also it has been proved that the engines of these boats can be driven noiselessly, a most important desideratum when they may be engaged on reconnoitring or cutting out expeditions; and orders issued from the Admiralty direct that all such boats in future supplied to her Majesty's ships are to be fitted with the engines working on the noiseless principle. The builder to the Admiralty of these steam life-boat launches and pinnaces, Mr. John Samuel White, of East Cowes, Isle of Wight, has sent in to Portsmouth Dockyard during the past week four pinnaces, Nos. 8, 9, 10 and 13, under his contract with the Admiralty, which have since been put through their trials by the officials of the yard, and very satisfactory and successful results obtained. After passing through the water-pressure test, they were finally tried over the measured mile. Nos. 8, 9 and 10 are boats of about 37 ft. between perpendiculars, and are driven by single screw engines of six-horse power nominal. No. 8 was tried at a draught of water of 3 ft. $1\frac{1}{2}$ in. aft, and 2 ft. $4\frac{1}{2}$ in. forward. Her four-bladed common screw had a diameter of 2 ft. $9\frac{1}{2}$ in., a pitch of 4 ft., a length of $6\frac{3}{4}$ in., and an immersion of the upper edge of 1 in. The mean revolutions of the engines were 249.33, and the boat's mean speed 7.986 knots per hour. No. 9 was tried at the same draught of water as No. 8. Her four-bladed common screw had a diameter of 2 ft., a pitch of 4 ft., a length of $6\frac{7}{8}$ in., and an immersion of the upper edge of $2\frac{3}{4}$ in. The mean revolutions of the engines were 244.63, and the boat's mean speed was 7.988 knots per hour. No. 13 was tried at a draught of water of 3 ft. aft and 2 ft. $5\frac{1}{2}$ in. forward. Her four-bladed common screw had a diameter of 2 ft. $5\frac{1}{2}$ in., a pitch of 3 ft. 4 in., a length of $4\frac{7}{8}$ in., and an immersion of the upper edge of $3\frac{3}{4}$ in. The mean revolutions of the engines were 282.66, and the boat's mean speed 7.288 knots per hour. No. 10 was tried at a draught of water of 3 ft. aft and 2 ft. 8 in. forward. Her four-bladed common screw had a diameter of 2 ft. $9\frac{1}{4}$ in., a pitch of 4 ft. 2 in., a length of $6\frac{3}{4}$ in., and an immersion of the upper edge of $1\frac{5}{8}$ in. The mean revolutions of the engines was 249.5, and the boat's mean speed 8.040 knots per hour. It was boisterous weather when all the boats were tried over the measured mile. All four of the boats were very handsome and buoyant in their appearance when under full steam pressure in running over the measured mile.—*Army and Navy Gazette.*

THE VAVASSEUR GUN.—A steel 7-in. muzzle-loading gun, designed and built by Mr. J. Vavasseur, of the London Ordnance Works, Southwark, was recently submitted to a private trial, and, so far as could be judged by the eight rounds fired from it, with highly satisfactory results. The gun is made entirely of Firth's steel, the material from which the A tubes of the Woolwich heavy guns are formed.

The inner tube of the Vavasseur gun is similar to that of a service gun of the same caliber, and is covered for its whole length by an outer tube shrunk over the inner. This ring is in two lengths, the first reaching as far as the chamber, the second protecting the A tube from the chamber to the muzzle. Over the second tier is shrunk a series of steel hoops, which extend towards the muzzle of the gun. The trunnions are of wrought-iron, forged upon a wrought-iron band, which is shrunk over the gun, and the breech is closed by a steel cascable screwed into the end of the second or B tube, which forms the rear of the piece. The entire length is 123 in.; the length of bore is 111 in.; the external diameter at the muzzle is 12 in.; the diameter at the breech is 24.4 in.; the total weight, 5 tons 1 cwt.; the trunnions are so placed as to give a preponderance of $5\frac{1}{4}$ cwt. The rifling has an uniform twist of 1 in 35 calibers, and consists of three ribs, with a flat table one inch wide, and raised from the bore about two-tenths of an inch.

This gun is mounted on a steel carriage weighing 22 cwt., the slides being 12 ft long, and 32 cwt. in weight, making a total of 54 cwt. The recoil is absorbed by a coned disc working within an iron drum, the rotation of which is regulated by an adjustable brake strap, tightened by a screw provided with an index divided into tenths. The disc, which is of iron faced with wood, is placed at the forward end of the slides, and is mounted upon a square-threaded screw shaft, with a pitch of 30 in., and which traverses the whole length midway between the slides. One end of the screw shaft carries the disc, which is 14 in. in diameter and 2 in. wide, and which fits within the drum before mentioned. The under side of the carriage carries beneath it a nut working on the screw shaft. The recoil of the gun incident upon the firing, throws the nut upon the bearing side of the thread, and tightens the disc against the circumscribing drum, absorbing the force of the recoil as the nut traverses down the revolving shaft, with a rapidity regulated by the adjustment of the brake strap.

In running out the gun, the carriage is raised at the rear end upon the rollers off the slides by a handspike, the same motion, by a connecting link, throwing the running-out wheels into gear with a pinion inside the carriage, which works into a slotted rack cut into the side plate of the slide along its whole length. This gearing is worked by hand in the usual manner. So soon as the carriage begins to travel the friction brake is released, so that the disc and drum offer no resistance. When the carriage is xtended its full length it is lowered again on to the slides, and the running-out wheels are thrown out of gear.

The recent trials had for their object the testing of the carriage rather than the gun. The following table gives the results in a condensed form:

	Elevation.		Charge.	Compressor.	Recoil.	
	dog.	min.	lb.		ft.	in.
Round 1	5	3	14	7-10	3	7
" 2	5	3	14	13-20	4	0
" 3	5	3	22	15-20	2	5
" 4	5	3	22	29-40	2	11
" 5	8	0	22	7-10	3	8¼
" 6	8	0	22	7-10	3	6
" 7	8	0	22	7-10	3	4¼
" 8	2	30	22	4-5	1	0

The gun and carriage will be doubtless submitted to official trial, which will help to decide the comparative values of steel and iron as a material for heavy ordnanee. Experience has shown in the tests of the Woolwich guns that a steel tube reinforced strongly by a wrought-iron casing remains serviceable, after its bore has become flawed, and its material considerably weakened, by means of the tensile strength of the surrounding metal, whieh is exerted in the direction of the strain upon the steel tube. The saving of weight in steel ordnance does not represent a corresponding saving in cost. A lengthened experience must decide that a large balance remains in favor of steel as an exclusive material for guns before the Woolwich system of manufacture is superseded.—*Engineering.*

Comparative Casualties of War.—The *Revista Militar*, of Lisbon, contends that the perfecting of firearms, far from increasing the mortality in battles, has, on the contrary, diminished it, and alleges the following instances: At Austerlitz the French lost 14 per cent., and the Austrians and Prussians respectively 14 and 30 per cent. of their soldiers. At Moscow the French loss was 37, while the Russian loss was 44 per cent. At Wagram the casualties were, among the French 13, and amongst the Austrians 14 per cent. At Bautzen the French lost 13, the Russians and Prussians 14 per cent. At Waterloo the losses of the Allies were 31, and of the French 36 per cent. Then comes the contrast. At Magenta the French lost but 7 per cent. of their troops, and the Austrian percentage did not exceed 8, while at Solferino the losses of the combatants were 10 and 8 per cent. It is hardly fair to compare the battle of Murfreesborough with those of regular armies, but according to the report of Gen. Rosencranz, which caused some surprise at the time it was published, 20,000 discharges of cannon put only 728 men *hors de combat*, and out of 2,000,000 musket shots no more than 13,330 took effect. It thus took 27 cannon balls and 150 bullets, or about 252 lb. of metal to disable each soldier.

Trowel Bayonets.—The 200 patent trowel bayonets, which have been making at the Springfield armory, will soon be placed in the hands of troops for trial.

The British Iron-clad Fleet. Its Cost. According to a Parliamentary return just issued, it appears that the number of iron-plated ships afloat is thirty-four; there are also ten building. Of four floating batteries, two are not yet completed for sea. Of the number of armor-clad ships afloat, fourteen have iron hulls; the following are only partially armor-clad, viz: The Black Prince, with 28 guns, tonnage 6,109, horse power 1,250; Warrior, 32 guns, tonnage 6,109, horse-power 1,250; Defence, 16 guns, tonnage 3,720, horse-power 600; Resistance, 16 guns, tonnage 3,710, horse-power 600; Achilles, 26 guns, tonnage 6,121, horse-power 1,250; Hector, 18 guns, tonnage 4,089, horse-power 800; Valiant, 18 guns, tonnage 4,063, horse-power 800; Northumberland, 28 guns, tonnage 6,621, horse-power 1,350; Bellerophon, 15 guns, tonnage 4,270, horse-power 1,000; Hercules, 14 guns, tonnage 5,234, horse-power 1,200; Penelope, 11 guns, tonnage 3,096, horse-power 600; Waterwitch, 2 guns; Viper, 2 guns; Monarch, 7 guns. Five of those afloat with iron hulls are wholly armor-clad, viz: the Minotaur, with 26 guns, tonnage 6,621, horse-power 1,350; Agincourt, 28 guns, tonnage 6,621, horse-power 1,350; Prince Albert, 4 guns; Scorpion, 4 guns; Wivern, 4 guns. The Vixen, with 2 guns, has her hull built of both wood and iron, and is only partially armor-clad. Eight of the ships afloat have wooden hulls, but are wholly armor-clad, viz: the Royal Oak, with 24 guns, tonnage 4,056, horse-power 800; Prince Consort, 24 guns, tonnage 4,045, horse-power 1,000; Caledonia, 24 guns, tonnage 4,125, horse-power 1,000; Ocean, 24 guns, tonnage 4,407, horse-power 1,000; Lord Clyde, 24 guns, tonnage 4,067, horse-power 1,000; Lord Warden, 18 guns, tonnage 4,080, horse-power 1,000; Favorite, 10 guns, tonnage 2,094, horse-power 400; Royal Sovereign, 5 guns, tonnage 3,765, horse-power 800. Six of those afloat have wooden hulls, and are only partially armor-clad, viz: the Royal Alfred, with 18 guns, tonnage 4,068, horse-power 800; Zealous, 20 guns, tonnage 3,716, horse-power 800; Repulse, 12 guns, tonnage 3,749, horse-power 800; Pallas, 8 guns, tonnage 2,372, horse-power 600; Research, 4 guns; Enterprise, 4 guns. This formidable fleet of iron-clads afloat represents in the aggregate 520 guns. Out of the thirty-four vessels afloat thirteen are built on Mr. Reed's plan and five on Captain Coles's turret plan. The first cost of some of the iron vessels now complete, ineluding fittings, but exclusive of incidental and establishment charges, was as follows: Northumberland, £459,109; Minotaur, £452,827; Agincourt, £446,115; Achilles, £444,590; Warrior, £356,990; Black Prince, £357,-993; Bellerophon, £343,076; Prince Albert, £201,613. The cost of some of the wooden vessels was:—Lord Clyde, £273,824; Lord Warden, £316,837; Royal Alfred, £269,370; Ocean, £253,813; Caledonia, £264,658; Prince Consort, £226,995. Of the ten ships building, seven have iron hulls and are only partially armor-clad, viz: the Sultan, with 13 guns, tonnage 5,226, horse-power 1,200; the Captain, 6 guns, tonnage 4,272, horse-power 900; the Iron Duke, 14 guns, tonnage 3,774, horse-power 800; the Audacious, 14 guns, tonnage 3,774, horse power 800; the Invincible, 14 guns, tonnage 3,774, horse-power 800; the Vanguard, 14 guns, tonnage 3,774, horse-power 800; the Hotspur, 2 guns, tonnage 2,637, horse-power 600. The Glatton, with 2 guns, has an iron hull, and is wholly armor-clad. The Swiftsure and the Triumph have their hulls of iron sheathed with wood. They are to carry 14 guns each, with a tonnage for each vessel of 3,893; horse-power 800 each. These ten ships represent in the aggregate 107 guns. Two are to be built on Captain Coles' plan, and eight on Mr. Reed's plan. The estimated first cost of the Captain is £335,000, that of the Audacious £222,657, that of the Invincible £221,757, and that of the Vanguard £249,759. The names of the four floating batteries—three of which have iron hulls and are wholly armor-clad—are the Erebus, with 17 guns; the Terror, with 16 guns; and the Thunderbolt, with 16 guns; the Thunder, with 14 guns, has a wooden hull, but is wholly armor-clad. The first cost of these batteries is thus stated:—Erebus, £82,039; Terror, £80,726; Thunderbolt, £80,230; Thunder, £59,776. The above 48 ships and batteries represent in the aggregate 689 guns, and horse-power of 35,290.

THE WILSON GUN.—A contemporary states that this gun is on the bolt principle, and of the most simple, direct and rapid arrangement. It requires but two movements to open and close the breech for firing; or, in other words, four motions for drill—namely, opening, loading, closing, firing—a bar extractor attached to the body of the bolt withdrawing and ejecting the cartridge-case in the one act of withdrawing the breech bolt. This bolt is fixed in position by a locking, or double lugg handle, situated on its rear end, and having a motion of partial rotation on entering the shoe-cap as the breech is closed. It is thus self-locking and securing; the double luggs engaging with the solid sides of the shoe-cap sustains the bolts firmly against the recoil. The gun has neither external lock, hammer, nor other projections, but the bolt itself contains a piston or striker operated upon by a strong spiral spring, the spring being liberated by the trigger depressing a flat guide or retaining spring placed underneath the shoe. The firing arrangement is very properly supplemented with a trigger stop of exceedingly simple and effective construction—namely, a hinged flap or plate, which, turned against the shank of the trigger, absolutely prevents its movement in any direction to discharge the gun.

SEA-GOING TURRET SHIPS.—"Engineering" (March 12, 1869) illustrates a new vessel of this class, designed by Admiral Paris for the French navy. It is a ship to carry two heavy guns, but it has only one turret, and is protected by armor only 5.9 in. thick on the vertical sides of the ship, 1.57 in. on the outside bridge, and 1.18 in. on the interior. The vessel is specially designed to carry sails, and would have three masts, by which the somewhat scanty power provided would be helped out. The following are the principal dimensions of the design:

Length of hull at water line		224.68 ft.
Outside width		50.84 ft.
Proportion of width to length		1 to 4.3
Width of ship inside		29.52 ft.
Proportion between interior and exterior width		1 to 1.72
Outside diameter of turrets		26.24 ft.
Calculated draught of water fore and aft		16.40 ft.
Volume of parallelopipedon		187,301 cub. ft.
Surface of the circumscribed rectangle at water line		11,416 sq. ft.
Surface of the circumscribed rectangle at midship section		827.80 sq. ft.
Di placement		110,214 cub. ft.
Weight of displacement		3075 tons.
Immersed midship section		713.8 sq. ft.
Area at water line		8600 sq. ft.
Proportion.	Of the volume of the hull to the parallelopipedon	0.588
	Of the flotation surface, to the circumscribed rectangle	0.754
	Of the midship section, to the circumscribed rectangle	0.857
Height from the water level to upper bridge		10.16 ft.
Height from main deck to sill of turret ports		2.62 ft.
Height of turrets		19.35 ft.
Thickness of plate of the armored zone,		5.9 in.
Height above water line		1.96 ft.
Depth below water line		4.92 ft.
Total		7.88 ft.
Proportion of armor above and below the water		1 to 2.5
Weight		356 tons.
Number of towers		1
Height of armor on ditto		7.28 ft.
Thickness of plate		.984 in.
Weight of armor		78 tons.
Total surface of towers		806 sq. ft.
Weight of lower belt (3.28 ft. high and 1.18 in. thick)		58 tons.
Weight of upper ring (984 in. thick),		97 tons.
Total weight of towers		155 tons.
Total weight of armor		776 tons.
Nominal horse-power		400
Number of guns		2
Total weight of armor per gun		388 tons.

Summary of Weights.

Armor	776 tons.
Engines	324 tons.
Guns	80 tons.
Masts, sails, etc	50 tons.
Stores, etc.	40 tons.
Water and tanks	20 tons.
Miscellaneous	8 tons.
Machinery for turning turret	24 tons.
Coal at the estimated draught of water,	279 tons.
	1601 tons.

THE MONITORS.—The following comments are made by a correspondent, upon the article compiled from "Engineering," in the first number, page 33 of "Van Nostrand's Magazine:"

The article begins with a numbered statement of the "advantages of turret ship." Respecting statement No. 1, instead of having "no masts," monitors, whenever necessary, do have masts. Case, "Monadnock." Her sail-power was sufficient to propel her five knots in a good breeze. There is no difficulty in applying sails to monitors. An official sail draught for one of our large monitors shows a spread of some 15,000 square feet of canvas, sufficient to propel the vessel nine or ten knots in a good breeze. The fact (in case of a monitor) of "having its guns and much of its armor further inboard," is by no means the reason why the monitor "rolls less than the broadside ship." The chief reasons are the position of the *metacenter*, as compared with the center of gravity of vessel, and of the displacement. Think of the immense area of water line section of monitors compared with their *length* and *displacement*. As to facts (observed) in relation to comparative rolling of our monitor and British broadsides in equal weather, the broadsides roll through an arc *three times* greater, hence from this point alone the depth of armor of a monitor below water—for equality of impregnability—*need be but one-third that of a broadside.* Putting masts on a monitor of the height and weight necessary for respectable sailing-power does not raise the center of gravity of the *mast* sufficiently to have a perceptible effect on rol ing.

2d. Respecting "Engineering's" estimate of "advantages of the broadside system," No. 1 says "they can carry masts!" *Per contra*, monitors have carried, and can carry them with safety. The statement that "a ship with a high freeboard will roll through an angle at which a ship with a low freeboard would capsize, from the weight of water on one side of deck," must have been made without proper calculation, or else on improper models. The pressure (and it is a heavy one) which would produce a heel of 18° on the Bellerophon would not produce a heel on a monitor of similar displacement of 7° ! This is no guesswork, but fact—the result of easily-made calculation.

Next respecting "artificial ventilation." This is, in fact, the only way, in a sea-going vessel, that decent ventilation can be had in bad weather, and in good weather, even with a low freeboard "open air exercise" at sea is possible. Think of the atmosphere in the cabin of the best of the English ships in bad weather when they are compelled to screw everything up tight! "Artificial ventilation" is one of the chief features in the "Stevens' battery," and a first-class feature it is, too. The atmosphere on the berth-deck of a frigate like the Roanoko was, in bad weather, with hoods on the hatches, only comparable to the Black Hole of Calcutta. Artificial ventilation, for sea-going purposes, is an American invention, and John Bull cannot cough it down any more than he could a 15 in. shot with 100 lbs. charge, and some 13,000,000 ft. lbs. of *vis viva*, which McAdamized his 8 in. solid slab, 18 in. backing and inner skin. What will he do against a 20 in., with some 22,000,000 ft. lbs.? High freeboard and 22 million ft. lbs. in shot scarcely make a good comparison.

3d. "The ship with a high freeboard carries its guns higher out of water." With either a central fixed tower (guns in casement), or a turret, the guns may, if necessary, be carried equally high. I have seen a plan of turret which carries its gun 10 ft. from the water, and that, too, without adding much weight. The celebrated Bellerophon only carries her gun $9\frac{1}{2}$ ft.

4th. "Engineering" further says: "Yet consider for a moment what a ship Ericsson designed to build —the Dictator—to carry two guns in a single 24 ft. turret, 9 ft. high and 15 in. thick * * * has a tonnage of 3,000 and a displacement of 5,000 tons * * * the boilers have far more grate area and heating surface than any vessel in the English navy." Now, the Dictator's displacement is inside of 4,500. The mistake of 500 tons is more than enough to make the turret $3\frac{1}{2}$ ft. thick, and allow for two 20-inch guns inside of it. As her side armor is $10\frac{1}{2}$ in. iron, 40 to 42 in. oak, besides inner skin, what broadside vessel of double her displacements yet built could whip her?

FILTER VANS AND CARTS FOR INDIA.—The scarcity of good drinking water is well known to be one of the most serious hardships of our army in India. It is notorious to every one of Indian experience that the soldiers are occasionally dependent on supplies literally poisonous and unfit for use, and the prevalence of cholera and other diseases has been distinctly proved to have been attributable to this cause. The authorities are now examining an important invention, manufactured by Messrs. E. H. Bayley & Co., the large wheelwrights of Newington Causeway, designed with great skill to meet this great want, and which seems admirably adapted to the purpose. It consists of a bullock van or cart on springs, containing a galvanised iron cistern, capable of holding about 250 gallons of water. The van is surmounted by a portable pump, by means of which the cistern may be filled from a pond, stream, or other source of supply. As the water when first pumped in may be very impure, the sediment is made by a simple arrangement to fall into a separate well or trap at the bottom of the van, whence it is drawn off by a cock. The water thus partially purified, next passes by a pipe into a second well, where it flows underneath two large filters, through which it is forced to percolate upwards. The value of this system of filtration by ascension is obvious, as the thicker impurities do not rise in the water, and consequently are drawn off by a cock without approaching the filters at all. Should the water be very impure, it can, by an ingenious contrivance, be made to pass, first through one filter, and then the other, and thus be doubly purified. After passing through the filters, the purified water flows into reservoirs, whence it can be drawn off into drinking cans from a row of brass taps at the back of the van. As fast as the water is pumped in at one end of the van, it is thus drawn off pure and filtered at the other. The cistern is thoroughly protected by an outer casing from the rays of the sun and kept cool.

These vans will be useful in our own camps, but will be a great boon to the army in some parts of India. We understand the patentees have received considerable orders from various foreign governments. While the House of Commons spends millions on guns and fortifications, it will assuredly not bogrudge the few thousands that will suffice for supplying every regiment in India with what will be invaluable for the health and lives of our countrymen.—*Army and Navy Gazette.*

EFFECT OF THE CHASSEPOT BULLET—ERRONEOUS REPORTS.—Dr. Gason, of Rome, reports as follows regarding the effect of different bullets at the engagement at Mentana, in November, 1867: The lightness of the Chassepot firelock and its loading at the breech caused a far greater proportion of wounds in the upper part of the body than was the case in those wounded by balls from the muzzle-loaders.—The entrance made by the Chassepot ball was very small; the exit not much larger. There was much less effusion of blood beneath the skin than in wounds by tho round ball or Miuié. The long bones were more frequently split. The immediate effects of the Chassepot were more fatal; but the ulterior effects less severe and fatal in wounds produced by the Chassepot than in these of the round ball or Minié. The external hemorrhage was greater in wounds produced by the Chassepot ball than by any other form of projectile; and in those places where the Italians fell when struck by it, there were large pools of blood.

Among the cases brought into the hospitals in Rome, there was not one where the wound produced by the Chassepot bullet bore any proportion to that mentioned in the report from the camp at Lyons—that "the exit was as large as a person's two fists." It would appear from the reports from the camp at Lyons, that in most instances the bodies of dead animals were used for the experiments.—*The Lancet.*

THE FRENCH NAVY.—The French fleet was composed on the 31st December, 1868, of 430 vessels, of which 331 were steamers with a total of 76,165 horse power. There are, besides, in course of completion afloat, 7 others of 3,710 horse power, and on the stocks 31 more of 12,405 horse power, and one sailing transport. This total is divided into two distinct portions, the first including the vessels which form part of the new fleet, to bo constituted in accordance with the programme in course of execution since 1857; and the second, composed of the remains of the old navy, considered unfit to take place in the new, either directly or after transformation. The new naval force, the only one that constitutes the real maritime strength of the empire, counts as completed 314 steamers and 10 sailing vessels. A table shows: (1) iron-clads to the number of 50 of various classes; (2) the unarmored fighting ships, 96 screw steamers; (3) 91 small steamers, despatch boats, tenders, &c.; (4) transports, 95 of various sizes; and finally, the two training schools, one for gunners and the other for naval pupils. Of the old fleet there still remain 17 steamers and 29 sailing ships.

ARMOR PLATES, made by coiling bars of iron as for Armstrong gun tubes, welding the coil by upsetting, cutting the coil in two, and flattening out the halves into plates, has proved a great failure, as the experts prophesied. The welds were found very defective.

THE NEW CHALMERS TARGET.—The recent death of Mr. James Chalmers lent a melancholy interest to the experiments which were lately carried out at Shoeburyness, with the last target designed by that gentleman. Although considerable hopes were entertained of the new target, they were not realized on the present occasion, the target having been pierced in every direction with the projectiles which were directed against it. Our readers are so well acquainted with the details of the Chalmers target, that it is unnecessary here to repeat them. It will be sufficient to state that the target lately experimented on was 15 ft. long, by 9 ft. high, the face being composed of two $4\frac{1}{2}$ in. armour plates of the same length as the target, and 4 ft. 6 in. deep. The target was 2 ft. $9\frac{1}{4}$ in. thick, including the angle iron ribs at the back. Mr. Chalmers had introduced eight modifications of backing, so that the target was divisible into as many different parts, each representing a modification of the general principle. A "Warrior" target had been made, and was placed beside it for enabling comparative results to be ascertained. The firing was from a 9-inch muzzle-loading rifled gun, with 250 lb. projectiles and 43 lb. powder charges, the range being 200 yards. As the trial, unfortunately, proved only the failure of the Chalmers target, it is unnecessary to follow closely the details of firing. Eight rounds in all were fired, five with solid shot and three with live shell. Rounds 1, 4, and 5 with solid shot were directed against the "Warrior" target, through which they failed to pass. Round 1 knocked a piece out of the edge of the target, and rounds 4 and 5 penetrated the target, but remained in it. Rounds 2 and 3 with solid shot were fired at the Chalmers target, through which they passed clean out to the rear. The first live shell struck the "Warrior" target, making a hole 2·23 inches deep, whilst the second and third shells passed through the Chalmers target, and burst in the rear. It was thus made apparent that the face plate of the latter target was much too weak for the work it was designed to do, and that in effect Mr. Chalmers had pushed his principle of elasticity too far. There is no question of the soundness of the principle, but the extreme lightness of the outer plate neutralized any effect obtainable from the backing. It is to be regretted that such a mistake in the designs of this target should have been made, and still more that the inventor is not here to profit by it, and to bring the labor of years to a successful issue.—*Mechanics' Magazine.*

THE HERCULES AT SEA.—Satisfactory reports have been received of the performances of the iron-clad Hercules on her voyage to Lisbon. Although dragging her large screw propeller, she several times exceeded a speed of ten knots under canvass, and performed the operation of "staying" with great ease. The whole consumption of coal upon the voyage was less than fifty tons, or one-twelfth of the quantity on board. She is also a very steady ship, rolling and pitching exceedingly little, not only under a press of canvass, but with a beam-sea running and little wind. The huge guns (each weighing 18 tons) were worked and fought every day with perfect success.

ENGLISH OAK—THE WOODEN WALLS OF ENGLAND.—The timber-built unarmed screw frigate Sutlej, is now having her machinery taken out at Portmouth, preparatory to being broken up. It was only in October, 1860, that the Sutlej made her first speed trial as a new ship over the measured mile, when she attained a mean rate of 13.076 knots. She was then considered one of the handsomest and swiftest ships afloat. She is now a striking illustration of the short life and costliness of a wooden-built ship of war.

A NEW NEEDLE GUN.—The Berlin correspondent of The London "Daily News," writes on Jan. 9: About a week ago the "Vossische Zeitung" astonished its readers with a paragraph announcing the invention of a new rifle, called the Zundwassergewehr, or ignition water gun. Although the experience of the last few years has prepared us for all sorts of wonders in the way of firearms, yet ignition water seemed an enigma which could only be solved by the man who knows how to set the Thames on fire. The passage was copied in other papers, and will probably excite no little interest in other parts of the world, until the prosaic explanation of a misprint has cleared up the difficulty. The real name of the invention in question is a "Zundmessergewehr," or an ignition knife gun. It appears that the cartridge is made of some peculiar kind of paper, and that it explodes when cut by a knife. This sounds very dangerous, but I must assume that a knowledge of the details would show that the ignition is not so simple as it seems. Lieut. Col. Count Lehndorf, one of the King's Adjutants, has tried the new rifle at the Hasenhaide range, near Berlin, in company of the inventor, Herr Meyhofer, a Prussian country gentleman, and the results were very satisfactory. Herr Meyhofer succeeded, in two experiments, in hitting the target 13 times in 36 seconds. Another wonderful invention is reported from St. Petersburg. A Russian officer has constructed a cannon which can fire 200 shots in a minute. It is extremely easy to handle, and very effective up to 1,800 yards.

A NEW GUNPOWDER.—A new composition of gunpowder is being tried in the French army and navy. The inventor, a M. Dessignolle, has substituted for sulphur the picrate or nitro-carbonate of potassa. The picric acid is a new compound, obtained from the mixture of phenic and nitric acids. The picric acid explodes by the heat, and there results nitrogen, carbonic acid, hydrogen, water, carbon and carbonate of potassa.

$$(C_{12}H_2K(A_2O_4)_3O_2 = 3Az + 5CO_2 + HO + H + 6C + KO\,CO_2)$$

The smoke produced is trifling, and the absence of sulphur makes it injurious neither to the men nor to the weapons. Besides that, when the powder is made only from picrate and nitrate of potash without carbon, a very violent powder is obtained, which is excellent for blasting. It has nearly the same strength as the nitro-glycerine, and seems to be less dangerous. The absence of smoke will be a notable improvement for tunnelling. It is probable that, when regularly manufactured, this new powder will be obtained at the same price as the ordinary gunpowder.

NOVEL GUN CARRIAGE.—A gun carriage and slide of a novel and very ingenious construction, by Messrs. Vavasseur, of the London Ordnance Works, for a 7-inch steel built-up rifled gun, was tested recently at Yarmouth, with the highest success. The compressor, which is the most important feature, consists of a cone and drum, working under a brakestrap, this friction gear being attached to the head of a long screw-shaft, actuated by a nut under the carriage, moving along it and turning it round. The great value of the system is that the compressor is always ready to be acted upon by the recoil, and is automatically put into gear the moment the gun carriage begins to move.

DEPTFORD DOCKYARD, which will be closed this year, is one of the most ancient dockyards in the kingdom—an old monastery, bearing date 1513, still stands in the yard, and is used as a storehouse. It was at Deptford Dockyard that Peter the Great learned the art of shipbuilding. The present strength in the yard is under 500 hands. The regular working strength is 841.

COST OF HEAVY GUNS.—The Ordnance Committee have discovered that the army Rodman 15-inch gun costs $6,500 each, for 49,000 lb. weight. The navy guns of the same caliber weighed 42,000 lb. The difference in weight, at 13 cents per pound, makes $910, which the navy paid more for their guns than was paid by the army. The navy contract with the Fort Pitt Foundry provided for the delivery of all guns on the seaboard at the expense of the maker, yet the Government paid for all this transportation. From the spring of 1864, all 15-inch guns procured at Pittsburg were taken without any powder proof, according to an order from the Chief of Ordnance. Therefore, guns procured since that time have been mounted in fortifications on expensive iron carriages, without being fired at all; and lately an order was issued from the Ordnance Department to subject them to a proof of charges of 100 lb. of powder, at the risk of the Government.—*Washington telegram to Philadelphia Inquirer.*

ORDNANCE AFFAIRS AT WOOLWICH ARSENAL.—Arrangements are being made for the construction of iron gun carriages for the navy at the Chatham Dockyard, though recently certain buildings in the Royal Carriage Department, Royal Arsenal, had been altered and fitted up with plant and machinery to carry on the works at a great cost. The removal of the naval carriages to Chatham will lead to part of the Carriage Department being closed. In the Royal Gun Factory Department, the Armstrong branch has been shut up for a considerable time with all its expensive machinery, in consequence of a large order being given for the conversion of guns from the smooth bore into rifled guns upon the Palliser principle, to be effected at the Elswick Factory, instead of at the Government establishment at Woolwich.—*Mechanics' Magazine.*

PALLISER'S PROJECTILES.—In a recent report of the Ordnance Select Committee are the following results of the penetrative power of shot and shell, fired from heavy rifled guns at a range of 70 yards. A Palliser shell weighing 398 lb., fired from a 10-in. muzzle-loader of 18 tons, with a charge of 54 lb. of powder, penetrated through 23 ft. of earthen parapet, and passing out in an upward direction continued its flight for 300 yards beyond. A 9-in. Palliser shot, weighing 248 lb., fired from a 9-in. 12 ton muzzle-loading gun with a 37 lb. charge, nearly passed through 23 ft. of earthwork, the point of the shot showing through the further side of the parapet.

KRUPP'S CANNON FOR PRUSSIA.—A large order for the 9-inch cannon which performed such extraordinary feats at Tegel has been given Mr. Krupp by the Prussian Government. The bill is expected to amount to 4,000,000 thalers, each barrel costing somewhere about 30,000 thalers. The same gun has just been adopted by the Belgian Government, to be placed on the walls of Antwerp. According to official intelligence received here, experiments made with the 9-inch cannon in Belgium resulted in the Bellerophon target being totally destroyed after eight rounds, the Warrior target having endured but seven.

AUSTRIAN IRON-CLAD.—The largest iron-clad in the Austrian navy—the largest ship probably ever launched in the Adriatic—has just been launched at Trieste. She is called the Lissa. The ship is built entirely of Austrian materials, and every detail of her machinery and armament will be Austrian. Her length is 272 ft.; breadth, 45 feet; displacement, 6,000 tons. Here engines are of 1,000-horse power, and her armament will be twelve 300-pounder Krupp guns.

NEW BOOKS.

A RUDIMENTARY TREATISE ON THE MANUFACTURE OF BRICKS AND TILES; CONTAINING AN OUTLINE OF THE PRINCIPLES OF BRICKMAKING. By EDWARD DOBSON, A. I. C. E., M. I. B. A. Revised and corrected by CHARLES TOMLINSON, F. R. S. Fourth edition. With additions by ROBERT MALLET, A. M., F. R. S., M. I. C. E., &c. With illustrations. London: Virtue & Co. New York: Virtue & Yorston. 1868.

The name of the author of this treatise is a sufficient guarantee that the contents will answer the expectations of the reader. If the "claims of long descent" are supposed to be of any importance to a building material, then bricks certainly take the foremost rank, and in all probability their future career will be as endurable as their past. It is true that the employment of stone, where works of great magnitude are concerned, becomes almost imperative, both for constructive reasons, as well as for the sake of æsthetical effect; but it will never supersede the more ancient material in structures of a smaller and less pretentious character. That there is an enormous amount of bad brickwork hourly erected in London and elsewhere, no one who is acquainted with the manner in which houses are run up by speculating builders will for a moment deny. At the same time, there are not wanting numerous examples of the same description of work which have withstood for centuries the attacks of the weather and the influence of time, and remain to the present day indisputable witnesses to the solidity and durability that is, or rather was, possible to obtain by that method of construction. But in those earlier times bricks were bricks and mortar was mortar. Mud and slime were unknown quantities.

As might be reasonably anticipated, it was not long after the introduction of machinery before its potent aid was called in to assist in the manufacture of bricks, and so far as their crushing strength is concerned, it appears that the machine-made brick will stand about one and a half times the weight that will crush the best hand-made specimens. In the manufacture of bricks, as well as in all artificial preparations, the success of the operation and the value of the product are chiefly dependent upon the selection of the material; consequently the selection and the preparation of the clay of which the bricks are composed demands not merely care and attention, but also experience on the part of the manufacturer. Next to this, the management of the kiln is an important detail in the process. From chapter I, which treats of the manufacture of bricks and tiles in Holland, and which is contributed by Hyde Clark, C. E., it seems upwards of a million bricks are sometimes burnt in a Dutch kiln. The Dutch have long been famous for their clinkers and other bricks of a hard description. Notwithstanding that the principle of brickmaking is everywhere identical, a great diversity exists in the various lesser operations connected with their production. The nature and extent of these vary with the district and locality where the manufacture is carried on, and the several methods practiced in the vicinity of the metropolis, in Nottingham, Staffordshire and other provinces, are fully described and investigated.

In addition to the regular established manufacture of these materials of construction at well known places, they are frequently made in large numbers in what might be termed an impromptu manner. Wherever any great excavation takes place, such as that for a large tunnel or dock, which requires to be "lined," the bricks for "lining" it are generally made upon the spot, provided that the earth be in any way suitable for the purpose. All that is wanted in a brick intended for tunnels, docks and other engineering works is, that it should be hard and sound, should ring well when struck, and not be too absorbent. Irregularity in shape and want of uniformity in color, however detrimental to house bricks, are of little or no consequence where strength and stability are the only featuros sought for in the building they compose. Chapter IX is devoted to a description of the different machines invented for facilitating brickmaking, and is well deserving the perusal of all interested in the subject. The illustrations are especially well executed, and are distributed with no sparing hand. In the appendix at the close of this valuable little volume there is a short chapter upon the science of brickmaking, in which the chemical nature of the operations, the composition of the various clays employed, and the effect of the combination of the several ingredients, are examined into. The publishers, in the production of the fourth edition of this well known treatise, have fully sustained in every point the acknowledged reputation of their firm, and also the value of the "Rudimentary Series."—*The Engineer.*

A TREATISE ON OPTICS, OR LIGHT AND SIGHT, THEORETICALLY AND PRACTICALLY TREATED, WITH THE APPLICATION TO FINE ART AND INDUSTRIAL PURSUITS. By E. NUGENT, C. E., Ex-principal of Commercial, Nautical and Engineering College, New York. London: Virtue & Co. New York: Virtue & Yorston.

This Treatise on Optics, by Mr. Nugent, is just one of those books calculated to demonstrate that the principles of this science, and, in fact, of any other, may be taught in a manner that can be readily comprehended, both by persons of limited information and of limited abilities. It must not be gathered from our statements that we recommend, or at all indorse, an unstudious or dilettante style of perusing a treatise on a scientific topic. * * * Starting with the definition of light, Mr. Nugent briefly refers to the various theories—ancient and modern—entertained upon that question, and it will be sufficient to remark that the wave or undulatory theory is now the usually received one among scientific men. It is true that the emissive theory still has its advocates, but it no longer meets with the universal acceptance it once did. The three chapters immediately following the first are devoted to an elucidation of dioptrics, or that branch of the science relating to the refraction of light. By the aid of several excellent diagrams the subject is fully and lucidly explained, including the formation of images by prisms and lenses. The one principal law of catoptrics, or that branch embracing the reflection of light, is that the angle of incidence is equal to the angle of reflection; and when this is understood, all the questions relating to the reflection of mirrors will be easily comprehended.

After perusing the chapter on caustic curves, which are practically and familiarly explained, we are introduced to physical optics, including the composition of light. This is one of the most interesting portions of the volume, and the various opinions put forward, and the experiments bearing upon the sevenfold or threefold composition of light, candidly and fairly investigated. Most of our readers are familiar with tho solar spectrum, which, according to Newton, consisted of seven, and to Sir David Brewster, of only three primary colors, red, yellow and blue. The latter philosopher accounts for the mistake into which he considers his scientific predecessor to have fallen, by attributing it to some imperfection in the manner of conducting his experiments. Be this as it may, the composition of white light may be regarded as consisting of the three colors only. A description of the eye, together with the laws of vision, and color-blindness, absorb chapter VIII. Under the head of "Optical Instruments" are explained most of those pleasing delusions, including the celebrated "Pepper's ghost." The details of the various descriptions of telescopes—the Newtonian, Gregorian, Gallilean and Herschellian—are illustrated by suitable diagrams, and a chapter upon the application of optics to the useful arts brings to a close this valuable addendum to our repertoire of books calculated to diffuse information and instruction among our artisans, and all who desire to become acquainted with the true principles of science. We may congratulate the publishers upon having produced a volume handy in size, neat in appearance both externally and internally, and admirably adapted for fulfilling the purpose which the author mentions in his preface was that which he had in view.—*The Engineer.*

SCIENTIFIC STUDIES; OR, PRACTICAL, IN CONTRAST WITH CHIMERICAL, PURSUITS: EXEMPLIFIED IN TWO POPULAR LECTURES. By HENRY DIRCKS, C. E., LL.D. Post 8vo. E. & F. N. Spon.

The first of these lectures is on the Life of the Marquis of Worcester; the second on Chimeras of Science. We have here an epitome of Mr. Dircks' larger memoir of the Marquis of Worcester, bringing together for the first time, in a popular form, what has never hitherto been accomplished; that is, a truthful notice of facts in connection with the life of the undoubted inventor of the steam-engine. Previously it had been the custom to supply every hiatus with some vague surmise or other, and, as each writer exercised his ingenuity as best he could, it became at length difficult to ascertain where the truth lay. Some declared he wrote his "Century" while confined in the Tower, others supposed he wrote it in France; Mr. Dircks shows that he wrote it after his release from imprisonment.

Mr. Dircks seems to be quite at home on the Chimeras of Science. He refers to various works on astrology, alchemy, and mathematical and mechanical chimeras, not omitting his own "Perpetuum Mobile; or, History of the Search for Self-Motive Power"—a work likely to be highly useful to young mechanics at their studies, and to older ones who have neglected them. Mr. Dircks concludes that—"Astrology is merely a philosophism, being empirical, wholly visionary, a mere fanciful system, compounded of incongruous mixtures of astronomical with human events, of mythology with theology, and of facts with pure fiction;" and that, while laying claim to the remotest antiquity, it makes no pretence to inspiration. Treating on alchemy, the author states that—"Alchemical writings are very numerous; they may be estimated at from 3,000 to 4,000 works, and an astonishing number of manuscripts." So insinuating was this delusion that Lord Bacon, Luther, Spinoza, Leibnitz, and many eminent moderns believed in finding the philosopher's stone, the gem of the Hermetic philosophy. Next follow the squaring the circle, duplication of the cube, trisection of an angle, and perpetuum mobile, illustrated by means of neatly engraved diagrams, to accompanying explanations. Among the squarers preference has been given to Mr. James Smith, of Liverpool, in plate 3. Arago declared that all that could be gained in computing "the area of the space included within a circle of thirty-eight millions of leagues radius may be determined within such a degree of precision that the probable error shall not exceed the space of a mite," or grain of sand, as others remark.

These lectures, notwithstanding their popular character, are replete with information, and cannot be read by the studious without satisfaction and benefit, as their author brings to bear on them a vast store of curious reading, and the result of years of practical experience.—*Mining Journal.*

COURS ÉLÉMENTAIRE DE PHYSIQUE. Par l'ABBÉ H. CABIAC. Paris.

THE LATHE AND ITS USES, OR INSTRUCTION IN THE ART OF TURNING WOOD AND METAL. (Anonymous.) 1 vol. 8vo. London: Trühner & Co., 1868.

A TREATISE ON LATHES AND TURNING. By W. H. NORTHCOTT. 1 vol. 8vo. Illustrated. London: Longmans, 1868.

There is no need to say much more of the second-named work than that it is a plainly written, unpretending and practical introduction to the use of the lathe, and instruction as to what may be done with it or by it, directly or indirectly. It deals not in the history or past phases of the turner's art, hut with the actualities of the present day; and is illustrated, among other plates, with some views of lathes, &c., produced from photographs furnished by some of the very hest makers, such as Fairhairn, Kennedy and Naylor, of Leeds, &c. This would be a good book to put into the hands of a lad commencing his apprenticeship in a tool-making or engineering shop. The first-named volume is still better—more exhaustive, and, we may say, a more scientifically written work, and hetter fitted for the advanced student of mechanical engineering. The author, who is prohahly an American, curiously enough thinks proper to conceal his name. He admits in his preface that a considerable proportion of his work consists in compilation from American journals; it may not he a hit the worse for this, however.

There are two appendices; one on the angles of tools, by Mr. Dodsworth Haydon, of Guilford; the other on a new arrangement of lathe and chuck to do rose engine work, by Elias Taylor, of Brighton. These, both hy English authors apparently, are well written, and the latter is useful to the ornamental turner.

As to fine-spun theoretic dicta for fixing the angles of tools for various sorts of work, we confess we have not much respect for them, notwithstanding the names of Willis and Bahbage, Holtzapffel, &c., with which such refinements have heen connected. All of practical value on the subject of these angles can he stated in a few senteuces, and hecomes insensibly learnt hy tact very soon by everybody. A razor, a wood knife, a wood chisel, a chipper for iron, a turning tool or drill, need different angles of edge; but we know so little of the nature of the resistance to division opposed hy solids, or of the arrangements of their constituent molecules, that theory really decides little or nothing worth knowing as to the *limits* of best angle for various materials and different conditions.

The fact is, a turning tool, for example, will cut nearly any metal in the lathe at many angles of edge between 60° and 90°, and by varying speed and other conditions of application of the tool, and holding the latter with mechanical firmness, the same results may be ohtained with larger variations of angle. For finisbing *soft* hrass the doctors fix the angle as 90°, *i. e.* a square scraping tool; but for turning *hard* steel or chilled cast iron the same, 90°, is not only the best hut the only angle that will stand long. Where is the *principle* that gets at these extremes? The fact is, much as has heen written—prattled, we are almost tempted to say—by theoretic amateurs on this suhject, the very fundamental hasis for any sound theory upon it remains to he discovered.—*Practical Mechanic's Journal.*

A PRACTICAL TREATISE ON MINE ENGINEERING. By G. C. GREENWELL, F. G. S. Second edition. London: Spon, 1869.

The first edition of this work was published fifteen years ago, and Messrs. Spon are doing good service in giving the world a second edition of a very valuable treatise, almost entirely rewritten, and puhlished in monthly parts. It is always difficult to judge of the merits of a book from a small instalment of the whole; hut Mr. Greenwell's reputation is one guarantee that the work will be good; the character of the first monthly part, now hefore us, is another, and Messrs. Spon's well-earned reputation is a third. The puhlishers supply a short prospectus, telling the world what the contents of the work are to be, viz: Geology, as applied to mining; classes of rocks commonly met with in mining for salt, coal and metallic ores; huilding materials; dykes, slips and mineral veins; internal heat; metallic ores and minerals associated therewith and with coal; smelting; boring and sinking tools; timbering; walling; tubhing; management of quicksands and clay; pumping engines and pumps; winding engines; ropes; pulleys; strength of timber; ropes and other materials; the working of mines; copper; lead; tin; iron; salt; coal; ventilation; theory and practice; fire damp; carbonic acid and other gases; explosions and other casualties, &c. The work will be illustrated with sixty-four large colored lithographs, four of which are contained in the first part. We must reserve a more extended notice of the work till it has made further progress towards completion. For the present it must suffice to say that Mr. Greenwell's information is accurate, and his style remarkahly easy, and even elegant, while the style in which the work is got up by the publishers leaves little to be desired. —*The Engineer.*

SYSTEM OF NAVAL DEFENCES. By JAMES B. EADS, C. E. Report to the Honorahle Gideon Welles, Secretary of the Navy. New York: D. Van Nostrand. 1868.

At the close of the American war, Mr. James B. Eads, an American engineer and shipbuilder, was commissioned to examine the naval constructions of Europe, and to report thereon to the Secretary of the United States Navy. The result of Mr. Eads' investigations were emhodied in this report. In this document, after touching generally upon the question of naval construction, and paying a well merited compliment to Mr. E. J. Reed, our Chief Constructor, in respect of the "Bellerophon," the author goes on to criticise the turret system. But the gist of the report is the puhlication of the author's designs for having from one to five fixed turrets within which the gun platform revolves. Mr. Eads of course falls foul of Captain Coles and Captain Ericsson, considering the deck joint a radical defect. On the whole, the "report" is not what we expected to find it, considering its title. It is true the author suhmits it as "the result of his observations ahroad," but having been commissioned "to examine the naval constructions of Europe," we should have expected something more than a little generalizing ahout European turret ships—which could be done hy the author in his own office—and a great deal of particularizing ahout his own scheme.—*Mechanic's Magazine.*

The "Army and Navy Gazette" gives a long *resumé* of Mr. Eads' arguments, and compliments him on his forcible style of statement, but expresses no opinion on the merits of the case.

BRITISH RAILWAYS — AS THEY ARE AND AS THEY MIGHT BE. By JOHN IMRAY, C. E. London: E. & F. N. Spon, 48 Charing Cross. 1869.

Various schemes for vastly increasing the number of passengers hy decreasing fares, and thus in the long run benefitting both the companies and the public, have been put forward. They are all too far advanced for our country and perhaps for our day. Mr. Imray's is less revolutionary than some that have heen proposed, and the following ahstract of it from the "Building News" will at least he entertaining:

The tickets for passengers to be issued hy Government, like postago or receipt stamps, to be sold at any stamp or post office, and available on any day and on any line. The tickets to be of two diffrent forms, and four colors—white for first class, red for second class, blue for third class, and yellow for luggage and parcels, these last to be adhesive. Square tickets to indicate a "short" journey, not exceeding twenty-five miles, and oblong tickets to indicate a "long" journey, over any distance greater than twenty-five miles. Every passenger while in a carriage to wear his tickets visibly attached by a hook or catch in his dress, so that the officers may see it. The prices of these tickets to be as follows:

	1st class.	*2d.*	*3d.*
Square tickets for short journeys..	1s.	6d.	3d.
Oblong tickets for long journeys...	16s.	8s.	4s.

Luggage tickets for any distance, 1s. each.

In cases where a line of railway belongs to two companies, and the first part traveled by a passenger does not extend twenty-five miles beyond a station where the passenger enters, the tickets to be collected and kept by the second company. In the case of long tickets the same system, but the second company to carry the passenger on to a distance of one hundred miles from the station where he started. Every railway company is to keep an account with a Government office — preferably a branch of the Inland Revenue Office — where the company is to obtain payment for its obliterated tickets, less a certain amount chargeable for duty.

CASSELL'S TECHNICAL MANUALS: ORTHOGRAPHIC AND ISOMETRICAL PROJECTION, DEVELOPMENT OF SURFACES, AND PENETRATION OF SOLIDS, &c. By ELLIS A. DAVIDSON, Lecturer on Science and Art in the City of London Middle Class Schools, and author of "Linear Drawing." Cassell, Petter & Galpin: London and New York.

A knowledge of orthographic projection is essential before the student can make working drawings of any bridge, house, roof or other example of construction, and this knowledge is only to be acquired by practically drawing the various diagrams and projections upon a tolerably large scale. * * *

This little volume commences with a description of the mathematical instruments ordinarily required by draughtsmen, and we heartily indorse the advice of the author, wherein he cautions his readers against bad and inferior instruments. It is always money well spent to buy the best tools, and no sensible person would ever think of doing otherwise. From the projection of single figures, the reader is gradually introduced to others of a more complicated nature, including the development of the cylinder and the helix. The last chapter treats on isometrical projection, a particular description of perspective delineation invented nearly fifty years ago by Professor Farish, of Cambridge. This is a very useful and at the same time a very characteristic style of drawing. It is admirably adapted for showing at a glance the *tout ensemble* of any architectural or engineering structure, the details of iron work or carpentry, and the general arrangement of details. At the same time it is not calculated to supply, strictly speaking, the place of working drawings. From the manner in which orthographic and isometric projectious are treated in the volume uuder notice, we consider it well calculated to form a valuable little text-book for the draughtsman and beginner.—*Building News.*

A DESCRIPTIVE TREATISE ON MATHEMATICAL DRAWING INSTRUMENTS, THEIR CONSTRUCTION, USES, QUALITIES, SELECTION, PRESERVATION, AND SUGGESTIONS FOR IMPROVEMENTS; WITH HINTS UPON DRAWING AND COLORING. By WM. FORD STANLEY. (Second edition.) Stanley: London.

This is a second edition of Mr. Stanley's treatise on mathematical instruments, to which several additions have been made. Amongst other things a description is added of a drawing board in the form of a tray for holding wood blocks while drawings are being made on them; and a new form of copying table, consisting of a sheet of glass, on which the drawing to be copied is placed, a mirror being arranged below the glass so as to throw the light up through the drawing. A description is also added of Amsler's planimeter, an instrument that deserves to be more generally known, and of a form of set square used on the continent for drawing section lines. This set square is provided with an arrangement such that by pressing a lever with the finger the square is shifted a certain distance. Altogether, Mr. Stanley's book contains much information that will render it useful to young draughtsmen.—*Engineering.*

AN ELEMENTARY COURSE OF PLANE GEOMETRY. By RICHARD WORMELL, M. A., Medallist in Mathematics and Natural Philosophy (London), author of "Arithmetic for Schools and Colleges." London: Thomas Murby, 32 Bouverie street, Fleet street, E. C.

In reviewing this book the "Building News" says the author of this volume has succeeded in investing a dry subject with a considerable amount of practical attraction, and illustrates each point by an appeal to the common sense of the student, in a manner that at once enlists his interest and arrests his attention. Lines and planes, angles, circles and triangles are described in detail, and the T-square, the level, plumb line, and square introduced, to show the application they have to the rudiments of other branches of education, and how they bear upon many points of technical and professional training. At the end of every chapter a number of questions for self-examination are added, sufficient to enable the learner to fix, by means of their solution, the substance of the chapter in his memory.

THE MANAGEMENT OF STEEL. By GEO. EDE; employed at the Royal Gun Factories' Department, Woolwich arsenal. From the fourth London edition. New York: D. Appleton & Co., 1867.

The successive editions of this little manual have gradually increased from a small pamphlet to a goodly duodecimo of over two hundred pages, and we aro glad to find that a reprint is accessible to our American workmen. As a practical worker in steel Mr. Ede stands very high, and his book affords evidence that he possesses the rarest of all faculties, viz: the ability to state plain facts in a plain manner. The result is that the book is crammed full of thoroughly practical directions and valuable suggestions.

Those who have carefully read the volume will, we think, agree with us when we say that, notwithstanding the unqualified praise which we have accorded to this book, it might be much improved if submitted to the editorial revision of some well-qualified person. In this way certain inelegancies, and consequently indefiniteness of expression, might be readily amended.—*Am. Journal of Mining.*

TREATISE ON VALVE-GEARS, WITH SPECIAL CONSIDERATION OF THE LINK-MOTIONS OF LOCOMOTIVE ENGINES. By DR. GUSTAV ZEUNER. Third edition, revised and enlarged. Translated from the German by MORITZ MULLER. London: E. & F. N. Spon.

Dr. Zeuner's treatise has been received on the continent as the standard work on valve-gear. The work is divided in all into ten chapters, devoted to the consideration of the simple valve-gear, and to the link-motions of Stephenson, Gooch, Allan, Heusinger von Waldegg, and Pius Fink, and the valve-gears of Gonzenbach, Meyer and Polonceau. There is also an appendix of the book, treating of the counter-effect of steam in engines fitted with reversing gear.

Dr. Zeuner's valve diagram was described and illustrated in the first number (page 20) of *Van Nostrand's Magazine.*

ENGINEERING FACTS AND FIGURES FOR 1868. London and Edinburgh: A. Fullarton & Co. 1869.

The sixth annual volume of "Engineering Facts and Figures" is now before us, and is no whit behind its predecessors. We need hardly state that the object of the work is to present a register of the progress in mechanical engineering and construction during each year. A leading feature in the present volume is a notice of the International Maritime Exhibition, held at Havre last year, and which was specially visited for the purposes of the work. Some additional notes are given on the Exhibition held in Paris in 1867, which tend to complete the subjects discussed in the previous volume. The matter is, as usual, arranged and classified under distinctive headings. The chief subjects considered are boilers, explosions, furnaces, fuel, steam engines, locomotives, marine engines and machinery in general, metals, railways and ships. Of course there is not room for everything in such a volume; but the selection of matter is admirably made, and the most important points of the various subjects are given, reference being made to the object from which the information is obtained, as a guide to the reader, should he desire further details. The volume is amply illustrated, and is got up in the usual neat style.—*Mechanic's Magazine.*

LOCOMOTIVE ENGINEERING AND THE MECHANISM OF RAILWAYS: A TREATISE ON THE PRINCIPLES AND CONSTRUCTION OF THE LOCOMOTIVE ENGINE, RAILWAY CARRIAGES AND RAILWAY PLANT. By ZERAH COLBURN, C. E. London and Glasgow: Wm. Collins' Sons & Co. New York: John Wiley, 535 Broadway. 1869.

One of the standing inquiries of students and experts in railway machinery has been, since 1865, "When will the remaining numbers of Colburn's Locomotive Engineering appear?" Nos. 13 and 14 are now before us. The subjects treated are The Link Motion, Combustion, Functions of the Locomotive Boiler and the Principles of the Blast. It is unnecessary to state that these subjects are ably treated. Mr. Colburn has been thoroughly fitted by his long experience as a practical locomotive engineer, and by his training as a student and writer on railway machinery, to handle these subjects in a manner at once thoroughly useful, sound and entertaining. Some of the chapters in these numbers were written by Mr. Ferdinand Kohn, whose work on the Iron and Steel Manufacture is noticed elsewhere. They were, of course, supervised by Mr. Colburn. We shall make further reference to this work as it proceeds.

ANNALES INDUSTRIELLES, PUBLIÉES PAR FREDUREAU, H. DE CHAVANNES ET CIE. A. CASSAGNES, Directeur. Paris, Rue le Peletier.

This is a new French bi-monthly engineering journal. So far this publication promises exceedingly well, and appears to be ably edited. It is, moreover, got up in very good style, each number being illustrated by carefully executed lithographic plates in addition to minor wood cuts interspersed in the text. The plates are of large size, and represent both civil and mechanical engineering subjects.

RAILWAY TRAVELING IN THE NINETEENTH CENTURY, WITH PLAN OF PROPOSED IMPROVEMENTS. By GEORGE LANSDOWN. London: Pettitt & Co., 23 Frith street, Soho. 1869.

This is a pamphlet advocating the American system of passenger cars for British lines.

LAXTON'S BUILDERS' PRICE BOOK FOR 1869, containing about 70,000 prices. London: Morgan & Chase, 1869.

TREATISE ON THE POWER OF WATER AS APPLIED TO DRIVE FLOUR MILLS, AND TO GIVE MOTION TO TURBINES AND OTHER HYDROSTATIC ENGINES. By JOSEPH GLYNN, F. R. S. Third Edition. Revised and Enlarged. New York: D. Van Nostrand. 1869.

It is a pleasure to see an old and valued friend, like this little work by Mr. Glynn, maintaining its well deserved popularity, and reaching a third edition besides an American reprint. The range of subjects treated in this volume is very wide, and almost all the data required in calculations relating to the flow of water; horizontal water wheels; turbines; undershot, overshot and breast wheels; water pressure engines and water rams, &c., are given very fully, and in such a shape that they can be readily used by the practical man. The publishers have certainly laid both students and practical men under deep obligations by this reprint.—*American Journal of Mining.*

THE TRANSACTIONS OF THE SOCIETY OF ENGINEERS FOR 1867. 1 vol. 8vo., with many plates. London: Spon, 1868.

This, the last volume of transactions of this thriving young society, quite maintains the character of its predecessors, and something more, as several of the papers are less of a mere elementary character—having just a little of the smack of schoolboy exercise about them, as was the case with a few of the former ones—and two or three are really able and exhaustive. This is especially true of Mr. Baldwin's paper on "Safety Valves," Mr. V. Pendred on "Tube Boilers," and, above all, Mr. S. W. Worssam on "Mechanical Saws." The volume, like all of the series, is got up in excellent style by the publisher; no clearer or better illustrations need be sought than the lithographs, which equal above a third of the volume in bulk.—*Practical Mechanic's Journal.*

IRON AND STEEL MANUFACTURE: A SERIES OF PAPERS ON THE MANUFACTURE AND PROPERTIES OF IRON AND STEEL; WITH REPORTS ON IRON AND STEEL IN THE PARIS EXHIBITION, ETC., AND DESCRIPTIONS OF MANY OF THE PRINCIPAL IRON AND STEEL WORKS IN GREAT BRITAIN AND ON THE CONTINENT. By FERDINAND KOHN, C. E. London: William Mackenzie, Paternoster-row.

This appears to us, upon cursory examination, to be one of the most complete and useful works extant upon modern iron and steel making. It brings the subject down to the present practice—however long that may last—and is very fully and well illustrated. It is favorably reviewed by the London "Mining Journal," and other professional periodicals. We shall give the work a more extended notice on another occasion. Meanwhile we advise mill managers and thorough students to procure it and review it themselves.

MURRAY'S TREATISE ON THE MARINE ENGINE. Fourth edition. London: Virtue & Co.

This is the treatise as to the publication of which the author, Mr. Murray, has so justly complained in the public papers. It was a good treatise for its time, probably, when first published, but needed much to bring up its leeway. This, the author complains, has been done or attempted by another hand, employed without his knowledge or sanction by the publishers, and whose work the author views as having by no means added to the value of his original. In that we are obliged to agree with the author. The book ought simply to have been reprinted as it stood, or all but rewritten, and not merely padded out by a bulky appendix, of which almost every page has been taken from easily accessible printed documents, &c.

RAILWAY NOTES.

Re-Rolling Old Railway Iron.*—The worn-out rails on the Erie and Pennsylvania Railways are re-rolled for further use in the same form, and this process is performed according to the following instructions, which are embodied in the specifications of that company:

1st. The old rails shall be piled in piles, and every piece shall be the whole length of the pile, and the pile so made shall be rolled into flats.

2d. All rails classed as 64 lb. to 67 lb. shall be rolled from a 9 in. rail pile, said pile to be made as follows:

3d. The said flats shall be put into a pile of proper size for a rail, each flat being of the full length of the pile, and of which flats the bar forming top or head of the rail shall be of a new, good, tough, granular re-worked iron, such as will weld well; to be $1\frac{1}{4}$ in. thick.

4th. The layers forming the central part or stem of the rail shall be of puddled or re-worked iron, of a good quality, or of old rails (at the option of the manufacturer), rolled to a thickness of not over $\frac{7}{8}$ in., and of such width that the various layers will break joints, and what is known as a staggered pile formed.

5th. The base of the pile, from which the bottom or flange of the rail is made, shall be of good, re-worked fibrous iron—the under layer of which shall be of full width and length of pile, not less than $1\frac{7}{8}$ in. thick. The pile shall be well and carefully heated, so as to insure a good weld.

6th. The short pieces furnished by the railway company, and all short pieces cut off by the rolling mill, shall be piled by themselves, and rolled into a flat, which flat shall either be piled in the rail pile or used in making flanges of the rail. The railway company shall have the right, from time to time, to direct in what part of said pile said flats, so made of the pieces shall be placed; not more than two such flats shall be in any one pile.

7th. The rails to be rolled to pattern furnished by railway company; to be 25 ft. long; not over ten per cent shall be of shorter lengths, but not less than 18 ft.; all rails to be undercut $\frac{1}{8}$ in.; to be notched $2\frac{1}{2}$ in. from each end, the notch to be $\frac{1}{2}$ in. deep and $\frac{7}{8}$ in. long, or of such dimensions as the railway superintendent may direct.

8th. It is mutually agreed that the railway company shall not exact from the iron works rails classed as re-rolled, to be of better material in the central parts and base of the pile than can be produced from the old iron furnished by said railway.

9th. Rails and process of manufacture shall be subject to inspection by such persons as the superintendent of the railway shall select and appoint for that purpose.

Mont Cenis Tunnel Completion.—According to Italian journals, the completion of the great tunnel is to be the occasion of a great International Exposition at Turin. The Government is to ask Parliament to vote the sum of 3,000,000 francs to cover the expenses of this enterprise. It is expected that the work will be finished in the winter of 1869-70, and that its use will begin early in the latter year. —*Annales du Génie Civil.*

* We copy this from an English paper, but we believe it first appeared in one of our own Journals; we have not the means at hand to give proper credit.

French Railways — New Company — Particulars of Works.—The larger part of the French railways are worked by five or six large companies; but recently many small local lines have been granted to new companies, who receive subsidies from the local authorities, and are free from many heavy regulations ordered by the Government to the great companies. A new company has thus contracted with the Conseil-général du Department de l'Hérault for 120 miles of new lines from Montpelier to the seaside, from Pezenas to Beziers, and from Montpelier to Lodeve. The company will receive a subsidy of £4,800 per mile. There will be only two classes of carriages, with the fares of the second and third classes of the main lines. The gauge will be the ordinary narrow gauge, the shortest radius of the curves will be 300 feet, and the inclines will not exceed one thirty-third. There will be no fences to the line nor guards to the level crossings, but the speed will not exceed fifteen miles an hour. The weight of the flat bottom rails will be forty-nine pounds per yard, and the average distance of the sleepers will be four feet. The rails are manufactured by the L'Horme Ironworks, near St. Etienne, at £9 15s. per ton. It is intended that the goods wagons of the main line should be admitted on these branches, but the engines will be special tank engines, with four coupled wheels, and weighing sixteen tons, or twelve tons empty. These engines will be supplied by Graffenstaden, near Strasbourg. There will be also some double bogie engines, which are manufactured by the Fives-Lille Company. The carriages, built at Lyons, will have a longitudinal intercommunication; there will be also some two-story carriages for the little line from Montpelier to the seaside, where a large passenger traffic is very probable. These lines will not have large works of engineering except a lattice girder bridge, with five spans of 120 feet each, over the Hérault river.—*The Engineer.*

Proposed Tunnel between Ireland and Scotland.—A scheme has been proposed for uniting Ireland and Scotland by a submarine tunnel. The entrance to the railway tunnel by which it is to be accomplished on the Irish side is to be from a point about midway between Cusheden and Cushendall, on the coast of Antrim, and on the Scotch side at Glenstrone, from whence it would run through the head of the Mull of Cantyre. The total length of the tunnel under water would be fourteen miles three furlongs, and it is said that the ground through which it would have to be made is exactly suited for tunneling operations, and the sandstone for lining it can be had in any quantity on the Irish side. It is proposed to construct the tunnel for a single line only, the extreme depth being twenty-one feet, and the clear width at the level of the rails fifteen feet. The estimated time that would be occupied in completing the tunnel is, allowing for all contingencies, under six years, and the cost under four and a quarter millions. To pay a dividend of five per cent, the weekly earnings must be forty-two pounds per mile, and an estimate is appended to show that the gross earnings would be largely in excess of this amount, and that the mineral resources of the land in the immediate vicinity of the Irish end of the tunnel would be immensely developed.

Punch's approved method of communication between passenger and guard—a shilling.

The Delhi Railway, when completed, will establish an unbroken line of railway communication between Calcutta and Lahore, a distance of 1,300 miles. The contract for its construction, for $302\frac{1}{2}$ miles, was let in 1864. The commencement of the work was, however, delayed until 1865. At the present time the wells for the foundations of the larger bridges have been sunk to the required depth. This railway, besides frequently crossing canals, spans three large and celebrated rivers, the Jumna, the Sutlej, and the Beeas, besides one great mountain stream, the Gugger. The aggregate water-way required for these rivers amounts to upwards of two miles.—On the southern section of the railway, between Umballa and Ghazeeabad, which was formally opened in November, there are eight large bridges, and ten for minor streams, comprising fifteen spans, varying from 60 to 102 ft. in length. On the northern section, seven important bridges are completed. Of materials, 90,000 tons, including permanent way, bridge work, fencing, and plant have been sent from England since the spring of 1865 for the formation of this railway. The date fixed by contract for the completion of the whole line is the third of May, 1870.

Safety of Workmen in Tunnels.—A new system, affording a great security to the platelayers in the tunnels, is used in the Blaisy tunnel of the Paris and Marseilles line. This tunnel, 13,600 feet long, is sometimes very smoky, and the men had great difficulty in being properly warned of an approaching train. An insulated wire has been laid by the side of the tunnel five feet over the ground. The ganger of the platelayers is supplied with a portable electric bell that he must suspend to the wire in the neighborhood of the place where his men and himself are working. The electric communication is completed by an iron wedge inserted between two rails of the line, and connected by a wire to the electric bell. As soon as a train goes into the tunnel, the signalman of the clock system at the entrance of the tunnel sends an electric current in the wire and rings the bell continually until the signal "line clear" is received from the other end of the tunnel.—*The Engineer.*

Altitudes.—The highest point on the Central Pacific Railroad is in the summit of the Sierra Nevada, it being 7,042 feet above the level of the sea, and the next highest is Pepoup Pass, 6,180 feet above the level of the ocean, and 541 miles east of Sacramento, in the Goose creek range of mountains. The highest points on the Union Pacific are Green river, 6,145 feet above the level of the sea; Benton, 6,635; Laramie, 7,175; Sherman, 8,424; and Cheyenne, 7,040.

Peat for Locomotive Fuel.—The following results have been obtained on the Grand Trunk railroad in Canada: Number of miles run by train, 683; aggregate distance run by all the cars, 15,267; average number of cars per train, 22.4; peat consumed, 48,745 pounds; wood for same work, 105,187 pounds; number of miles run per ton of peat, 31.6; number of miles run per cord of maple wood, 27.6; experiment in favor of peat, 14 per cent.

A Railway in Persia, from Teheran to a suburb 6 miles out, is in progress.

Railway Time Tables in Holland.—We find in the Dutch journal "Opmerker" the following lines:

"*Bois-le-Duc.*—The provincial Court of Appeals has just given its decision upon a writ of error, from the tribunal of Breda, in the case of M. J. Urban, residing at Brussels. The tribunal found M. Urban guilty of a violation of the law of Aug. 21st, 1859, containing provisions for the management of railways, in failing to cause the departure of the Rozendaal train at the time indicated in the tables on the evening of Sept. 29th. M. Urban was fined 200 florins, and sentenced besides to six days in jail.

"The Court of Appeals has confirmed the judgment, and the appellent has been compelled to pay the costs."

M. J. Urban, we believe, is the director-general of the Grand Central Railway of Belgium, which has a station at Rozendaal. It seems that the Dutch Government requires railway time tables to be kept up to. Nobody will blame it in this case. —*Annales du Génie Civil.*

Abandonment of Broad Gauge.—The northern section of the Great Western Railway of England is now worked entirely upon the narrow (4 ft. $8\frac{1}{2}$ in.) gauge. The 7 ft. gauge is being gradually abandoned on the entire line.

Railways in Persia—The Shah of Persia has recently granted to English capitalists the monopoly of railroad building in that county for twenty years.

A Car is now building in Jersey City, which will be the costliest, the largest and one of the most elegant in the world. It is for the Erie road, and will cost $60,000.

MISCELLANEOUS.

Notice to our Cotemporaries.—Several technical journals are in the habit of copying without credit from "Van Nostrand's Magazine" translations from French and German magazines. We do not quite see the propriety of copying without credit our abstracts of papers and articles from the English journals; but when we have undertaken the expense and trouble of translating as well as compiling, we think an acknowledgment thereof, on the part of our said cotemporaries, would be at once just and polite.

New Books.—It may perhaps be unnecessary to call the attention of our readers to the series of notices under this heading. This is probably the most comprehensive list of new professional books that is accessible to the general reader; and the notices present not only sufficient specifications of the subjects treated, but the average professional opinion as to the manner in which they are treated.

A New Alloy.—A new alloy, forming, we are told, a beautiful white metal, very hard, and capable of taking a brilliant polish, is obtained by melting together about 70 parts of copper, 20 of nickel, $5\frac{1}{2}$ of zinc, and $4\frac{1}{2}$ of cadmium. It is, therefore, a kind of German silver, in which part of the zinc is replaced by cadmium. This alloy has been recently made in Paris for the manufacture of spoons and forks, which resemble articles of silver.

Wooden Pavements in California.—Not content with giving a fair trial to the widely-known Nicholson wood pavement, the Californians have devised several kinds of their own, two of which, known respectively as the Perry and the Stow pavements, have been tested to some extent in the streets of San Francisco. The Perry method consists in having the blocks sawed in such shape that when laid down they will occupy a position in which the grain of the wood, instead of being vertical, will lie in an inclined position, with V-shaped grooves or recesses arranged between their upper portions, and filled with gravel unmixed with asphaltum, or other waterproof or binding substance, this last being considered unnecessary. The grooves or recesses are caused to break joints, and are, of course, designed to facilitate the foothold of horses, &c., passing over the pavement. It is claimed that by this plan of laying the blocks the latter are caused to mutually sustain each other, that their surfaces are less subject to being battered and abraded by iron-shod hoofs and the tyres of wagon wheels, and that the expansion of the blocks consequent on the absorption of moisture, instead of causing the pavement to "arch," will simply make each block slide slightly upon the inclined surface of its neighbor. The blocks employed in the experiments thus far made with this kind of pavement, have been subjected to a preservative process, in which the pores of the wood are filled with sulphates of lime and iron. The Stow pavement resembles the Nicholson in the shape and size of its blocks; but instead of the plank foundation of the latter has provided underneath it a bed of sand. The sand is densely packed to support the blocks, and also the superincumbent pressure of travel thereon, by means of longitudinal rows of wedges driven down into the sand alternately with the several series of block. The great advantage of this system lies in the facility with which it may be taken up and replaced when desired, as, for instance, in the case of sewage repairs, &c. Akin to the subject of pavements is that of sidewalks, and in the construction of these asphaltum appears to be coming into very extended use in the Golden State. In San Francisco they are made as follows: Upon the sand is laid a foundation of boards, upon this is placed a layer of brick, and upon the brick is spread a cement which is constituted by asphaltum from Santa Barbara, mixed with ordinary gravel of fine texture.—*Engineering.*

Specimens of Large Belts.—Messrs. Hoyt Brothers, of New York city, have lately finished two very large belts, a portion of an order for the American Print Works of Fall River, Mass. One is 228 feet long and 38 inches wide, double; the other 107 feet long by 36 inches wide, also double, each about five-eighths of an inch in thickness. Weight of the larger belt 1,998 lbs., and of the smaller one 810 lbs. One hundred and fifty of the choicest "buts" were selected from 3,000 hides, themselves sorted from about 9,000. The leather of these belts is wholly from domestic cattle, and tanned with oak bark only, at the tannery of the company in Cumberland, Md., no extraneous acids or hot liquors being used. At first price the value of the largest belt would amount to over $2,800. The material and workmanship are certainly creditable to the manufacturers.—*Scientific American.*

The experiment of making belting from paper has proved a success in the hands of Crane & Co., at Dalton, Massachusetts, and the article is now used in all their own mills and several other manufacturing establishments. The belting resembles the genuine oak-tanned leather, and serves alike well in a dry or damp atmosphere.—*Engineer.*

The Late Ocean Steamship Race.—The City of Paris (Inman line) steamed from New York to Queenstown in 9 days 7 hours 23 minutes; stopped at Queenstown 20 minutes; steamed from Queenstown to Liverpool in 18 hours 27 minutes; total run, 10 days 2 hours 10 minutes.

The Russia (Cunard line) steamed from New York to Queenstown in 9 days 8 hours 5 minutes; stopped at Queenstown 23 minutes; steamed from Queenstown to Liverpool in 17 hours 12 minutes; total run, 10 days 1 hour 40 minutes.

The City of Paris won the race to Queenstown, beating the Russia by 42 minutes only. The Russia won from Queenstown to Liverpool, beating the City of Paris by 75 minutes, to which add 3 minutes longer stoppage at Queenstown; the Russia recovering her lost way, and winning by 33 minutes on the total distance steamed, which by the Russia's log was 3,066 miles in 10 days 1 hour 17 minutes, or about $12\frac{2}{3}$ miles per hour whilst under way in steaming.—*Cor. Engineer.*

A New Submarine Light.—An interesting experiment was recently made at the residence of Dr. Doremus, in New York city, in order to test the utility of a new method of illumination under water, invented by a lady—Mrs. Devoe—and designed to facilitate the various operations of submarine engineering. The plan, which has been patented by the inventor, or rather the "inventress," is simply this: Two rows of convex glasses are arranged in the side of a vessel below the water-line, and suitable lights—magnesium, calcium, or electric—are so arranged in relation with the glasses and with appropriate reflectors that the rays are thrown out into the water to illuminate the same. It is intende to use in conjunction with this apparatus a peculiarly constructed device by which objects in the water will be reflected upon a submerged mirror in such a way that the images may be perceived on looking down the tube or body of the instrument, which resembles that of an ordinary telescope.—*American Artisan.*

Preventive for "Dry Rot."—Builders, allotment gardeners, and others who employ home grown timber for fencing and other purposes, will be glad to hear that an effectual preventive for the "dry rot" has been discovered. The recipe is forwarded to the "Gardeners' Chronicle" by Mr. J. Baily Denton, and has been thoroughly tested by experiment. It consists in soaking the timber for a short time in lime-water. A pit or tank, or good-sized barrel, according to the extent of requirement, will answer the purpose, the lime being added to the water in the proportion of eighty-eight grains to one gallon. Timber creosoted in this way stands the weather remarkably well, and is not subject to the decay to which unprepared timber is so liable.

A New Light.—Mr. James Allison Hogg, gas engineer, Edinburgh, has discovered a method of producing intense light with coal gas by mixing it with atmospheric air. The mixture of gases is lighted after passing through a tissue of iridio-platina wire at a determined pressure. In a few seconds the metal becomes heated up to a white heat, the flame disappears, and an intense white light is the result. An enlarged picture has been taken by its aid on prepared photographic paper. The light will burn in a gale of wind without any protection round it, and a downpour of rain will not affect it.

Preserving Timber.—Dr. L. Feuchtwaner's process for the preservation of timber is simply to steam the timber, and then inject a solution of silicate of soda for eight hours, after which the wood is soaked for the same period in lime-water.—*Engineer.*

PERMANENT WAY.

REPORT OF THE STATE ENGINEER OF NEW YORK, PREPARED BY S. H. SWEET, DEPUTY.

From the advance sheets of the Report of the State Engineer and Surveyor of New York, on Railroads.

[Continued from page 388.]

STEEL RAILS—THE RESULTS.—Bessemer steel rails have been in regular and extensive use abroad, over ten years. For some five years large trial lots have been laid on various American roads having heavy traffic, and during the last two years importations have largely increased.

The manufacture of steel rails has also been commenced at four large establishments in this country, and some 7,000 tons of home manufacture have been produced and laid down. It is estimated that from 40,000 to 50,000 tons of steel rails are in use on our various railways. Among the users of steel rails are the Hudson River, Erie, and Pennsylvania railways — 10,000 tons or more each; the Lehigh and Susquehannah (entirely built of steel); also the Philadelphia & Baltimore; Camden & Amboy line; Lehigh Valley; New York Central; New York & New Haven; Naugatuck; Morris & Essex; Cumberland Valley; South Carolina; Chicago & Northwestern; Chicago & Rock Island; Chicago & Alton; Michigan Southern; Michigan Central; Lake Shore line; Chicago, Burlington & Quincy; Pittsburg, Fort Wayne & Chicago; also the Boston & Providence, Boston & Worcester, Boston & Maine, Boston & Albany, Eastern, Connecticut River and other lines in New England.

THE WEAR OF STEEL RAILS.—As no steel rails are reported to have worn out on our roads, the comparative durability of steel and iron cannot be absolutely determined.

The president of the Philadelphia & Baltimore railway states (in the letter before quoted) that the use of steel commenced in 1864, that the rails (25 miles in all) were laid on the most trying parts of the line; that none have been taken up on account of breakage, wear or defect; that upon the portion of the line near Philadelphia, the first steel rail imported had already worn out sixteen iron rails; and that none of the steel rails have shown any imperfection, but are all wearing smoothly and truly.

On the Pennsylvania railroad, the report of the Chief Engineer for 1868 states that 11,494 tons of steel rails had been purchased, and 9,956 tons laid. The first were laid in 1864. They are all wearing smoothly, showing no change except the slight diminution of section to be reasonably expected from the heavy traffic. No steel rails have yet worn out. The report of the Superintendent (Feb., 1869), says: "The use of steel rails continues, with satisfactory results, and 4,544 tons of this material have been laid since date of last report."

It is officially reported that on the Camden & Amboy line, some of the steel rails laid three years ago are now good in places where iron lasted but a few months.

The last report of the Engineer of the Lehigh Valley railway says: "Another year's wear has made no perceptible impression upon the 200 tons (of steel rails), the first of which was laid in May, 1864, none of which have broken or given out since last report. These rails have had a severe test, being in those places in the track where they are subject to the greatest wear, and being laid with a chair which is much inferior to the most approved joint now in use. There is no longer any possible doubt as to the superiority of steel over iron in economy, as in every other respect."

Unofficial reports from the Erie, Hudson River and other roads show that the above statements represent the average quality of steel rails.

The last report of the New York & New Haven railway states that "the subject of steel rails has received special attention, and after a careful investigation of all the points involved, it has been determined hereafter to make all renewals of track with steel rails only; 2,600 tons of Bessemer steel rails have been contracted for on account of renewals for the present year."

The report of the Morris & Essex railway for 1868 says: "During the last year one track through the tunnel has been relaid with steel"—also some 150 tons of steel laid elsewhere. "The wear of steel shows conclusively that economy will require its use on all heavy grades and sharp curves."

The last report of the New Jersey Railroad and Transportation Company says: "It is probable that steel rails will be gradually laid the entire length of the road, the greater durability of these rails, overcoming the objection to their increased cost.

Within the last three years, two notable papers have been read before the Institution of Civil Engineers, in London, upon the maintenance of way and the wear of rails—the papers of Mr. Price Williams and Mr. C. P. Sandberg. They were followed by prolonged discussions, in which the makers of iron rails took a conspicuous part, lecturing the engineers on professional subjects. The general facts and conclusions elicited have been published in the various engineering periodicals, and are extremely favorable to steel for lines of heavy traffic. A great number of instances of the comparative wear of steel were cited. In one case 23 iron rails had been worn out, where a steel rail, laid end to end with the iron, was not yet worn down. In other cases the wear was 17 to 1. It is conceded that any steel rail will outlast 6 iron rails. In fact, the remarkable wearing qualities of steel rails have never been doubted or questioned.

Breakage of Steel Rails.—Some steel rails of English, French and American manufacture have broken in service. In several cases the cause has been ascertained by the direct analysis of the broken rail. The cause was phosphorus. In some other cases, where analyses were not made, the general character of the iron used has been ascertained, and the trouble has been inferred to be phosphorus, or, in some cases, an excess of silicon. It is well known to steel makers that a very minute proportion of phosphorous (above .02 per cent) will make Bessemer steel brittle. In other cases, rails have broken at the mark of the "gag" or instrument for straightening the rail cold. The rails had not been properly hot straightened, or were finished at too low a heat. More rails have broken through punched fish-bolt holes and at punched nicks in the flange, than at any other places. Experiments prove that punching a hole in a steel rail sufficiently hard to wear well, weakens it. Three or four rails are reported to have broken, or rather crumbled, by reason of large flaws. Upon examination it was found in one case, that a steel rail end had been placed in the ingot mold, and that the liquid steel poured around it had not perfectly united to it. This practice in casting was therefore abandoned. In another case, a lump of clay appeared to have fallen into the mold and to have become cast into the ingot. In another case, too much of the fag end of the ingot had been left upon the rail—in other words, the rail had been sent out in an unfinished state. These causes of failure will be again referred to.

The *total* breakage of steel rails, in this country, and the comparative breakage of steel and iron have not been reported. The total breakage of steel on several roads has been officially reported.

Upon Jan. 1st, 1869, on the Hudson River railway, out of eleven thousand tons of steel rails in use, some of which had been laid three years, eleven rails had broken. The greater number of these rails were in use during the excessively cold winter 1867–8, when it was unofficially reported* that 113 iron rails broke in one day on this railway, and when it was officially stated that 1,000 iron rails broke in a month on the Erie railway.

On the Erie railway, out of 8,000 tons of steel rails in use Jan. 1, ten rails had broken. Some 800 tons of these rails were of American manufacture, and none of them have broken.

* "Engineering," March 27, 1868.

Upon the main line from New York to Philadelphia, a small quantity of steel rails were laid four years ago, and 200 tons of very slender steel rails, two years ago. The rest of the steel on this line was laid in 1868. Out of the entire 1,500 tons in use, one rail has broken.

Upon the Philadelphia, Wilmington and Baltimore railway, the President, Mr. Hinckley, states (in a letter before quoted) that out of 25 miles (say 2,400 tons) of steel rails "we have never broken one in use, nor taken up one on account of wear or defect."

The Chief Engineer of the Pennsylvania railroad reports that "some lots of American steel received have been found too hard and brittle, having a tendency to break easily; these have been carefully excluded from main tracks. The recent American steel rails furnished have been found fully equal in toughness and wear to the best foreign steel, having been subjected to severe tests under a falling weight."

On the other hand, a bad lot of steel rails have been removed from the track of the Reading railway, and the breaking of some steel rails on the Michigan Central railway is reported, although the use of steel is continued on that line. Mr. James F. Joy, President of the Chicago, Burlington and Quincy railway and of the Michigan Central railway, reports as follows, as to the use of steel rails (3 miles) on the former road: "The result has thus far not been such as to encourage the Board in an extended use of it in the ordinary track of the road." As to the results of 3 miles of steel on the Michigan Central, Mr. Joy says: "The steel rail thus far has hardly borne the test, having been found more liable to break than iron. As the average life of iron on the road is about 8 years, it is somewhat more than questionable if it will be found economical to substitute steel for iron in the track of the road. At stations and where the life of the iron is short from great wear, it is expedient, perhaps, to make the substitution."

It is a rather remarkable fact, however, that the Superintendent, Mr. H. E. Sargent, in the same report of the Michigan Central, says: "Three hundred tons of English steel rail, manufactured by John Brown & Co., after the Bessemer process, were laid early last year in some places where exposed to severe service. They have worked well thus far, hardly showing perceptible wear at any point."

In the absence of further official information, it is fair to assume that the breakage of steel rails is only a small percentage of the breakage of iron rails. Indeed, the latter is of daily occurrence, and is rarely considered by the public, except when lives are lost, and not always by railway managers when they make contracts.

Tests and Improvements.—The very important question now arises—Can steel rails be relied upon to give the satisfactory results above quoted, or improved results—can the evil of breaking be practically overcome?

We have seen that the chief and usual cause of brittleness is phosphorus. It is well known that the great deposits of iron ore in this country, such as the Iron Mountain and Lake Superior are practically free from this impurity. The quality of the ores in this and adjacent States is various. Those of the Housatonic valley are generally well adapted to steel making; the magnetic deposits of Lake Champlain are generally unsuitable. The cheap charcoal irons of Alabama, Virginia and Tennessee are generally very pure. The Cumberland irons of England, made especially for Bessemer steel, and used by Brown, Cammell and other first-class makers there, have also been imported to our steel works at reasonable rates. But however plentiful the ores suitable for steel may be in this country, great care in smelting and in the selection of fluxes will be indispensable to a uniform product. The manufacture of pig iron in this country has been so remunerative, that iron-masters have not heretofore felt impelled to introduce the refinements that characterize the smelting process abroad. A uniformly bad iron would, of course, be avoided by the steel-makers—the danger lies in the creeping in of impurities, by reason of improper manufacture, when the *general character of the iron is good.* This cause of failure may obviously be avoided.

Upon the introduction of the new manufacture in this country, our steel-makers appear to have made the natural but inexcusable mistake of neglecting analyses, critical inspections and rigid tests. This error was copied from the early English practice. In both cases it led to uncertain results, and injured the reputation of the product. Now it is reported by our steel-makers that they buy no irons until after they are specially analyzed; that they mix a large number of irons for each charge of steel, so that any accidental impurities in one may be largely diluted; that they test all charges of steel by welding, cold bending and otherwise; and that they test rail ends from each charge of steel made. One steel axle maker advertises that he makes *each* axle four feet longer than required, and tests it by dropping a 1,640 lb. weight 5 times upon this end from an height of 20 feet.

The punching of steel rails has been abandoned. Several kinds of power and hand drilling machines have been introduced, that do the work rapidly and well. The loss from the neutral axis of a rail, of the little material necessary to let a bolt through, cannot sensibly weaken it. To prevent the rails from creeping, the engineer of the Pennsylvania railway pins them to several sleepers by means of $\frac{1}{4}$ inch holes drilled in the flange. There are also other and better devices for preventing end movement, which do not weaken the rail at all.

The grand advantage of steel, for service under concussion and wear, is its homogeneity. Having been cast from a liquid state, it is sound and uniform, and free from the laminations and layers of cinder and numerous welds which characterize wrought iron, especially the low grades of wrought iron usually put into rails.

The tests above referred to would appear to amount to a guarantee against rails breaking in the track. The causes of failure mentioned, are obviously not a necessary feature of the Bessemer process, nor is uncertainty regarding the quality of the product an inherent difficulty. Perhaps no metallurgical process is more simple and less liable to variable features and results, *provided always* that the iron and the other materials and the machinery employed are of good quality Mistakes in the process of manufacture are of very rare occurrence, because it is less trouble to go right than to go wrong, and because the manufacture is in a very small degree dependent on the skill and judgment of the workmen. Melted cast iron is weighed into the converter, a steady blast is applied to it until the flame suddenly and unmistakably drops and changes color, indicating the complete removal of the carbon, and then a quantity of recarburizing material is added by weight. There is no guess work at any stage of the process, and the absolute determinations of the spectroscope may, if required, be employed as to the period of decarburization. Bad, refractory materials, impure coal, weak and fluctuating blast, and careless management of the casting, contribute to produce defective steel; but the chief uncertainty, in this country, has been in the pig iron. The experience of the Pennsylvania railway, before quoted, proves, however, that this difficulty has been avoided. And the results at the Cumberland furnaces, in England, are remarkable proofs that *uniformity* and excellence of quality are a simple question of blast furnace construction and management, when the coal and ores are reasonably pure. Notwithstanding the searching character of the tests referred to, the trial bar and the trial rail-end from each charge, it has been considered desirable to establish a still more certain and comprehensive system of tests, and to improve the manufacture by ascertaining the effects of different processes and treatment upon the ingots. To this end, preparations have been commenced at one of the steel works in this country, to determine, at whatever expense of time and money may be necessary—

1st. What reasonably rapid and convenient test of steel rails and axles will represent in kind (though, of course, exaggerating in degree) the test of actual service, The heavy weight falling upon the rail is objected to on various grounds. It does not prove that the rail will stand *numerous* blows accompanied by flexure, and it may prove that the rail is too soft to wear well.

2d. The exact effect of temperature upon the strength of steel of various grades.

3d. The effect of annealing upon the strength and durability of steel rails.

4th. The effect, as to strength and durability, of drawing down rails from ingots of large size, as compared with drawing them down from ingots of small size—the exact value of reduction.

5th. The comparative effect, as to strength and durability, of drawing the ingots, at the first stage, under the hammer or in the rolls. However valuable the effect of hammering may be upon wrought iron—squeezing out the cinder and perfecting the weld *in detail*—the conditions of steel are totally different. Steel has no cinder, and is already homogeneous, requiring no welds. It is, therefore, probable, that while hammering might make the mass a little more dense and hard, rolling would produce the more uniform structure and the more soft and ductile product.

6th. The uniformity of ingots from the same charge of steel. It is obvious that all parts of a ladle full of liquid steel, having been boiled together and thoroughly mixed, should be alike mechanically. Any chemical differences would be impossible at so high a temperature—some 5,000 deg. Fahr. Some experiments were recently made for the Central Railway of Orleans, to test this and other features of Bessemer steel.* The result showed the practical identity, not only of two ingots chosen at random from the same charge, but of the various charges under experiment.

Improved Traction upon Steel Rails.—It has been too much the practice of railway managers to consider only the increased durability of steel. A less striking, but perhaps equally important advantage, is that it has double the strength and more than double the stiffness of iron. Some three years since, Mr. George Berkley made, in England, above 600 tests of the stiffness of steel and iron rails of equal section. The rails were supported on 5 ft. bearings, and loaded with dead pressure at the middle. The first rails tried weighed 68 lb. per yard, and loads respectively of 20 tons and 30 tons were applied. The average of 427 tests of the Ebbw Vale Co.'s and two other standard makers of iron rails, gave, with 20 tons, a deflection of $\frac{5}{8}$ in. and a permanent set of $\frac{1}{2}$ in. With 30 tons the deflection was $2\frac{1}{5}$ in. and the permanent set $2\frac{1}{16}$ in. With Brown's steel rails, 45 tests gave an average deflection of but $\frac{5}{16}$ in. and a permanent set of $\frac{1}{8}$ in. With heavier rails and loads, the comparative stiffness of steel was still more marked. The great and constant resistance to traction, and the wear and tear of track, wheels and running gear, due to the deflection of rails between the sleepers, and the perpetual series of resulting concussions may be much reduced, or practically avoided, by the use of rails of twice the ordinary stiffness; in such a case, however, reasonably good ballasting and sleepers would be essential. When a whole series of sleepers sinks bodily into the mud, the consideration of deflection between the sleepers is a premature refinement. If the weight of steel rails is decreased in proportion to their strength, these advantages of cheaper traction and maintenance will not, of course, be realized. The best practice, here and abroad, is to use the same weight for steel as had been formerly employed for iron.

Steel-Headed Rails.—Many attempts have been made in England, on the Continent, and in this country, to produce a good steel-headed rail, and not without success. Puddled steel heads have all the structural defects of wrought iron, as they are not formed from a cast, and hence homogeneous mass, but are made by the wrought iron process, and are, in fact, a "high" steely wrought iron. They are, however, a great improvement upon ordinary iron, although probably little cheaper than cast steel heads. Rolling a plain cast steel slab upon an iron pile has not proved successful. The weld cannot be perfected, on so large a scale, and the steel peels off under the action of car wheels. Forming the steel slab with grooves, into which the iron would dovetail when the pile was rolled into a rail, has been quite successful. The greater part of some 500 tons of such rails, made in this country, and put down where they would be severely tested, about 4 years ago, have outworn some 3 iron rails. Others failed in the iron stem, which was too light, after a shorter service. Rolling small bars of steel into the head of an iron pile has been recently commenced at various mills in this country and in England. No conclusions are yet warranted by the short trial of these rails.

There is a growing feeling among engineers and steel-makers, that the compound rail, made wholly or partly of steel, will prove more safe and economical than any solid rail, and that the defects of the old compound iron rail, largely used in this State some years since, may be avoided, since these defects were chiefly due to the nature of the material. The experiments in this direction will be watched with great interest by railway managers, for if the same durability of track can be obtained with a steel cap as with an all steel rail, the first cost will be greatly decreased. A rail made in two or three continuous parts, breaking joints, is also a practical insurance against disaster from broken rails.

* See Van Nostrand's Magazine, Vol. I, page 104, for complete account of these experiments.

THE SIEMENS-MARTIN PROCESS.

We print below the particulars of a charge of Siemens-Martin steel, produced at the works of Messrs. Cooper, Hewitt & Co., at Trenton, under the superintendence of Mr. F. J. Slade, who introduced the process in this country. We are informed that the time of the process is often shorter, and the yield greater, but that this is a fair sample. Certainly not an unduly favorable one.

We have experimented with a bar of steel made by this process, exactly as represented in the following table, and have found it to be very soft and tough, and capable of sustaining a very high heat:

Martin Steel Process, April 21, 1869, 6.25 A. M. to 6.22 P. M.

CHARGE, 78: INGOTS, 543–560. CLASS I.

Time of charging.	West Cumberland Pig.	Franklinite Pig.	"A" Iron Re-carb.	Steel Scrap.	West Cumberland Flats Puddled.	Time of Taking Proofs.	Remarks.

METHOD OF ELECTRO-PLATING CAST IRON, BY PROF. DR. BÖTTGER.—One ounce of nitrate of silver is dissolved in 16 ounces of distilled water when boiling, and two ounces of cyanide of potassium are added. When these substances are completely dissolved, the fluid is mixed with a solution of one ounce of chloride of sodium in 48 ounces of water. The cast iron object to be plated must be free from oxide, and has to be cleansed by dipping it a few minutes into nitric acid of a specific gravity of 1.2, immediately before being plated. The plating is done in the above described solution, with the assistance of two or three galvanic elements of moderate strength.—*Polyt. Notizblatt.*

OUR TECHNICAL SCHOOLS.

THEIR DEVELOPMENT RATHER THAN THEIR INCREASE.

New England, which, though composed of six states, is, in many important respects a unit, has her *Chandler Scientific School* connected with Dartmouth College, N. H., and recently presented with forty thousand dollars, expressly to develop its course in civil engineering; her *Massachusetts Institute of Technology* at Boston, with an endowment—expended and appropriated—approaching, if not amounting to a million of dollars; her *Worcester School of Industrial Science*, with a total endowment approaching three hundred thousand dollars, and a well equipped machine shop, analogous, for the study of mechanical engineering, to a laboratory for the study of chemistry; her *Agricultural College* at Amherst, with an endowment of a third of a million dollars, and begging the State of Massachusetts for one hundred and fifty thousand more; her *Sheffield Scientific School* at New Haven, with an endowment recently stated at "only three hundred and twenty-seven thousand dollars," and her *Lawrence Scientific School* at Cambridge, Mass., also well endowed.

New York is probably not very far from equal to all New England, in extent, population and wealth, and she, accordingly, presents her quota so to speak of five schools of science. There are the *Rensselaer Polytechnic Institute* at Troy; the *Engineering Department at Union College*, Schenectady, the *Cooper Institute*, and the *School of Mines of Columbia College*, both in New York City; and the *Scientific Departments of the Cornell University* at Ithaca. This comparison by no means, implies that New York is doing little or nothing for *professional* Scientific instruction. It does, however, at this point, suggest the vital question: How can these worthy, and, some of them, long established *beginnings*, best be completed?

Within the brief limits of an article, this question can best be answered by a few preliminary general explanations, followed by a brief discussion of some one representative example.

"Scientific Schools," then, are, first, either simple or compound. By a simple school is meant one which gives but one professional course and degree. Medical schools, and schools of mining, only, are examples to the point. By a compound school, is meant one, which gives several parallel courses of study, and corresponding degrees. Such are nearly, or quite all scientific schools in the United States.

Again: from another point of view, the engineering, and other scientific schools of this country, are either independent, or component schools. The former are separate organizations. The latter are component parts of larger organizations. Thus, the *Institute of Technology* in Boston, and the *Polytechnic Institute* in Troy, are independent schools. The *Sheffield School* at New Haven, and the *Engineering Department* at Union College, are components of Yale College and of Union College.

Further: There is a marked difference between the technical schools, in respect of the requisite age for admission to them, considered as indicative of the relative elevation of their courses of study. Thus, boys of fourteen, are admitted to the Chandler Scientific School of Dartmouth College, while at Troy, the required age is nominally sixteen, and virtually over eighteen, as shown by the records for several recent years; and, as the two institutions are not known to come into any disadvantageous competition with each other, it may be said, not ungraciously, that a comparison of their published programmes will show a corresponding difference in the scope and range of the studies pursued.

Schools, again, differ greatly in relative wealth, as seen in the opening statements of this article, though, if we include moral elements, those institutions which are poorest in material things, may, like many individuals similarly conditioned, be the wealthiest in elements of power to shape and enrich and strengthen the minds which yield to their formative influence. There is, perhaps, no proposition concerning life, which does not need to be received with thoughtful discrimination; and it is certainly true that great invested resources, sumptuous edifices, and ample equipments, do not, of themselves, necessarily make a superior institution, while they *may* even have no better effect than the contemplation of Babylon had upon Nebuchadnezzar. Nor is this remark a jealous sneer at the wealthier institutions. Each one of them is welcome to all it asks for. The success, throughout the land, of the course of professional education in science, in which all the technical schools are alike engaged, is better than the success of any one school. It is only declared that the material resources of each institution, whether greater or less, are truly valuable or not, to it, and, through it, to the public, according to the purposes for which and the spirit and energy with which they are wielded.

Lastly: if only for the sake of doing honor to one of the ornaments of New York State, and, indeed of the Nation, it must be noted that scientific schools, like others, differ, as existing either on the principle of *reciprocity*, by which the student pays a sum partly, at least, representative of what the training received is worth to him; or on that of *benevolence*, by which the pure, earnest, and capable youth, who is appointed to do battle with poverty, is helped, by his stronger brother, to those things which are beyond the compass of his purse, but not beyond that of his mind.

The Rensselaer Institute heads the list of the former class of schools, by the high tuition which its uncompromising thoroughness enables it, and its lack of any invested endowment compels it to demand. The Cooper Institute of New York nobly represents, in the scientific field, the agencies which exist to give, to the struggling, a fair footing in life.

These radical grounds of distinction among schools, have so multiplied at our pen point, while it has traced them, that there is little space left in which to discuss actual examples, in the light of these distinctions.

We take the Institute at Troy as the best representative example, because, it is not only the oldest and best known in the country, but is also the ripest for a new reorganization. Founded as early as 1824, it has had upwards of four hundred graduates, nearly three hundred of whom are living, and many of whom have become, or are becoming distinguished. It has now in operation, though not on a large scale, three of its four proposed four years' courses; viz., that in civil engineering, for which it has long been especially celebrated; that in mining, recently established; and that in natural science. It only needs a comparatively moderate increase of men and means to enable it to meet the growing demand for its published course in mechanical engineering; since its admirable location, in a centre of varied manufacturing industry, furnishes it with actual machines at work, in place of costly cabinets of models, useful as these must everywhere be, to a certain extent. In its civil engineering course, also, it illustrates the superiority of practical examples over models, when the former can be had. A score or more of widely different wood and iron roof and bridge structures are right at hand, and on such a scale as to invite interested scientific investigation, or practice in drafting; while a noble river, with numerous islands; and a sharply defined bordering hill region, broken by many ravines, afford such practice in both topographical and hydrographical engineering field operations, as cannot so well be had in door yard exercises, or on prairie levels: In mentioning the ripeness of the Institute for a new re-organization, allusion is made to the fact that it was mainly a school of National Science—Geology, Botany, etc.,—until 1849, when it was re-organized as more distinctively an engineering school, with a course of two years; which, by a process of natural growth, quickly expanded to one of three, and, soon after, to one of four years. Also to the fact that, to-day, it is doubtless the ripest existing school of its kind in America for a re-organization with a five years' course, in two main divisions; first, an elevated preparatory course in general science and modern languages, of three years, to be followed by high and strictly professional courses of two years each, for the degrees already contemplated, and, in addition, a course in *Architecture and Building, both civil and naval.* Such a two fold five years' course, would doubtless ultimately expand to one of seven years: All of which taken in connection with the preceding principles, only leads directly to the conclusion, which it is the main object of this article to establish, viz., that with the existing number of *unfinished* scientific schools in the country, of which the Troy School, with all its characteristic advantages and disadvantages, is but one, it would be far better to develop to organic completeness these existing institutions than to further multiply costly experimental beginnings.

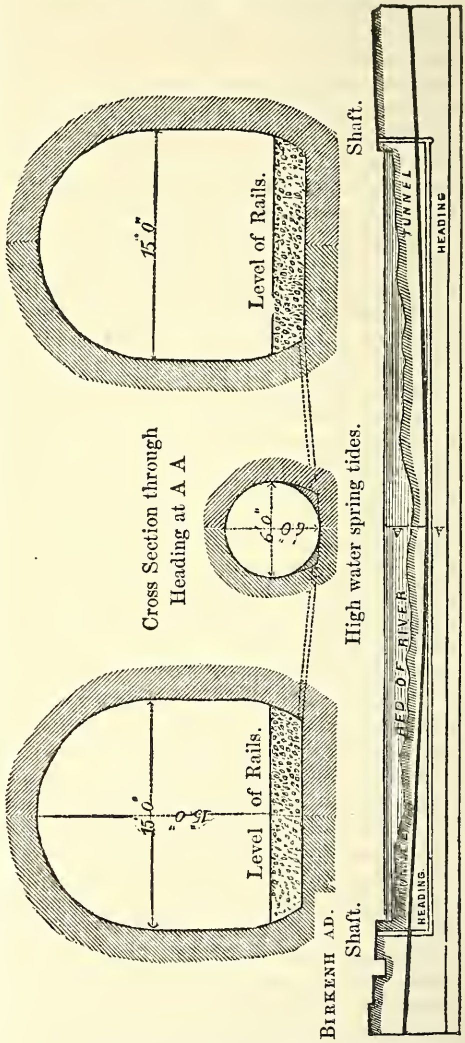
THE WROUGHT IRON MANUFACTURE.—We learn that anthracite coal slack, and even sand and ashes, have been substituted for ore, in the Ellershausen process, with good results. The decarburization was, of course effected by the fettling ore; the coal both separated the particles and increased the heat, thus facilitating the chemical reaction; the ashes and sand probably merely loosened and divided the mass for the better action of the fettling.

THE PROJECTED MERSEY TUNNEL FROM LIVERPOOL TO BIRKENHEAD.

PARTICULARS OF COST—CHICAGO TUNNEL AND OTHER WORKS.

By Sir CHARLES FOX.

From the "Quarterly Journal of Science."



As a means of inter-communication between Liverpool and Birkenhead, a tunnel beneath the Mersey has been under consideration by leading men on both sides of the river for upwards of thirty-eight years; and when the inconvenience and loss both of time and money which the want of such means of transit has ever occasioned are considered, it is, in these days of increased facilities, a matter of surprise that, while works of real difficulty have been carried to completion on every side, this obvious want should not have been satisfied.

There is but one opinion as to the importance of inter-communication between Liverpool and Birkenhead, and it being admitted that the great obstacle in the way of its realization is the doubt existing in the public mind as to the cost at which it can be attained, it has been felt that this doubt can never be overcome unless the nature of the river bed is conclusively proved.

When this has been done, I am sure that the construction of a tunnel through the red sandstone rock under the Mersey will be found an easy and inexpensive operation, as judging from the many similar works which have been executed in this rock during the last forty years, (those most analogous having been tunnels of various dimensions, carried on at considerable depth below the level of the bottom of the river, with a view of obtaining a more copious supply of water for the town of Liverpool,) it has been ascertained that in no material can such works be effected at so small a cost as through the very strata now well known to exist in this locality, the amorphous nature of the rock rendering it peculiarly advantageous for tunneling operations.

Tunnels have been made at a low price through chalk, as that material is readily excavated; but from its general looseness and its consequent tendency to fall, it is deemed necessary, for the purpose of ensuring safety, to put in brick or stone lining, and this, as compared with red sandstone, which generally requires no such lining, considerably augments the cost; and it must not be forgotten that the sandstone, when excavated from a tunnel in or near a town, is saleable for use as building material, while chalk taken from a tunnel, being of no value, is more generally run to spoil.

It would appear that one of the most formidable hindrances in the way of getting capitalists to embark their money in making tunnels under rivers, of which very many are urgently needed, arises from the disposition which undoubtedly exists to form an unfair comparison between such works and the Thames Tunnel, which, as every one conversant with the circumstances connected with it will know, cost a very large sum, although passing under a river of no considerable breadth. This, however, is no fair criterion upon which to judge of any other case. This tunnel was constructed some forty years since, when the science of tunnel making was but little understood, and when it had to be applied upon a very limited scale, without the advantages arising from many later improvements, and without the extensive experience derived during the last forty years from works of this nature, required in the development of the railway system all over the world.

This makes a comparison deceptive, to say nothing of the Thames Tunnel having to be constructed under all the difficulties of passing, not through London clay, which it would have done had it been placed a few feet deeper, but through the treacherous and loose silt and gravel of the bed of the river Thames, while the tunnel which forms the subject of this paper will pass through solid rock.

To attempt to draw a comparison between this project and the Thames Tunnel is but to show an entire want of acquaintance with the relative circumstances of the two cases, for it must be borne in mind that the Act authorizing the construction of the latter received the Royal Assent on June 24, 1824, more than forty-four years since, and that the tunnel was not opened for passenger traffic till March 25, 1843, having occupied a period of eighteen years and three-quarters in arriving at completion.

Were this work now taken in hand by an engineer possessing the experience obtained in constructing tunnels since the period above referred to, taking care to place his work deep enough to let it pierce only the London clay (to have done which the present tunnel ought to be fifteen feet deeper than it is), no doubt the entire work could be completed for little more than a tithe of the cost (which was £454,700), and need not certainly occupy a longer period than two years, as is proved by the following facts:

The excavation for the Thames Tunnel commenced in December, 1825, and all went on satisfactorily until May, 1827, when the upper portion of the works protruding above the London clay into the gravel and silt of the bed of the river, the first irruption of water took place, there being then a length of 545 ft. of the tunnel constructed, which had been done in a period of seventeen months; so that, had no casualty occurred, and assuming that the rate of progress was not, as it no doubt would have been, augmented by the natural increase which always follows a better knowledge of any work, the whole 1,200 ft. would have been completed within three years and two months; and this, be it remembered, would have been the result if made wholly from one end; whereas, with the present increased facilities and knowledge of the operation, it would have been carried on from both sides simultaneously, when, even at the then slow rate of progress, the time would be reduced to one year and seven months; so that there can be no doubt that, with present appliances, the work of the tunnel could, with perfect ease, be completed in one year and a quarter; and taking for the shafts and other matters, say, half a year more, the whole could with convenience be accomplished in one year and three-quarters.

In order to clear up every doubt, I propose, at an estimated cost of £20,000, to drive a heading under the Mersey from shore to shore, a distance of 1,300 yards, and thus not only to prove the practicable nature of the larger and more complete undertaking, but also the future cost, while at the same time providing the necessary drainage and ventilation for the permanent works.

The first operation will be to sink a shaft on either side of the river, on land belonging to the Mersey Docks Board, to a depth of about 120 ft. below the surface (see plate, lower figure). The shaft on the Liverpool side will, for a depth of say 40 ft., pass through made ground, and will then enter, and for the remainder of its length be entirely through, the solid rock. That on the Birkenhead side will be in solid rock throughout. These shafts will be about ten feet in diameter, and will terminate in large sumps for pumping purposes. At each end will be erected permanent pumping engines and pumps of sufficient power to deal with the largest quantity of water that is likely to be met with, and which pumps will not only be used during the construction of the works, but be adapted for keeping the main tunnels permanently free from water. Winding engines will also be erected of sufficient power, not only to deal with the material excavated from the heading, but also with that from the tunnel itself.

The shafts having been sunk to the full depth, and the machinery fixed, the heading will be commenced from either end, and driven much in the same way as an ordinary mining water level. It will have a very slight rise towards the middle of the river, so as to drain both ways into the shafts. Judging from experience, I expect that at least four yards lineal a day will be driven at either end, giving a total of 160 working days, or thereabouts, for the completion of the heading after the shafts are sunk. I have taken much pains to collect evidence as to the nature of the rock through which the heading will pass, and have found every one conversant with the subject unanimous upon the point. The general result of my inquiries and observations cannot be more forcibly explained than by the following summary of evidence given before the Referees of the House of Commons in 1865.

The late Mr. Thomas Duncan, then engineer to the Liverpool Waterworks, stated that he knew well the nature of the rock, which is not very porous. He did not think the quantity of water produced from the rock at Birkenhead and Liverpool would make the tunnel a difficult work of construction, and he did not believe there would be any difficulty in carrying it through, so far as water is concerned. He considered that the "faults" existing in the sandstone rock, and shown on the geological map, were advantageous, as he had cut through many of them (having excavated in the red sandstone at various points over sixty square miles), and had nearly always found them filled up with a species of concrete, which was perfectly water-tight. In a few instances, however, he had found them filled with laminated rock, having a saccharine appearance, and evidently having been subjected to a great heat, and yet water-tight.

Mr. James Abernethy, C. E., stated that, having been engineer to the Birkenhead Docks, he had large experience of the sandstone rock, of the same character as the rock excavated from the Birkenhead Docks, which is a close, compact, strong stone, suitable for building purposes.

Mr. John Fowler, C. E., stated that in framing his estimates he had well considered the question of possible faults in the rock, and, on the whole, preferred to have faults of the character known to exist in the red sandstone at Liverpool and Birkenhead, as they, being impervious to water, back up and limit in area the water contained in the interstices of the rock. The faults are filled either with clay or with some vitreous material. Mr. Fowler further stated that he considered red sandstone at all times the best material to construct tunnels through.

Besides the above testimony, there is the further fact that Mr. John Hawkshaw, C.E., F. R. S., proposes to construct a tunnel under the Mersey, near its mouth, where the river is very wide and the character of the rock less certain; and it is therefore evident that engineers of eminence are agreed in considering the work of making a tunnel thoroughly practicable, and that at a moderate cost.

As much doubt has been expressed as to the possibility of driving the heading for any such sum as £20,000, I would remark that the Trustees have before them a tender from a responsible contractor, who is prepared to undertake to complete the work considerably within that amount, finding all necessary plant and machinery, and giving approved security to the extent of £5,000.

Again, the chief item in the cost of this work is that of excavation, and the engineers already mentioned, and who gave evidence before the Referees, were agreed in considering 9s. a cubic yard an ample price for this work in the tunnel, including all possible contingencies, being, in fact, three times the cost of similar work under ordinary circumstances. I have, however, taken 20s. per cubic yard for the excavation in the heading, which I believe to be far more than it can cost.

That a tunnel, or, as it is called, a subway, can, in the estimation of those competent to form an opinion, be carried under the river Thames at a very small cost is, I think, proved by the fact that Parliament, last session, passed an Act for the "Lower Subway" proposed by Mr. P. W. Barlow, F. R. S., C. E., son of the highly talented Professor of Mechanics of that name, the capital for which is but £12,000, with power to borrow £4,000.

This work is now in course of construction, and is to consist of an excavation through the London clay 440 yds. in length, lined with cast iron cylinders $\frac{7}{8}''$ thick, with strengthened flanges, whose external diameter will be $7.1\frac{3}{4}''$, or 7 ft. inside. At each end there will be a vertical shaft between 50 and 60 ft. deep, fitted with lifts for the purpose of raising or lowering passengers from and to a saloon carriage, which will at very frequent intervals pass through the heading for the conveyance of passengers.

From each end the subway will fall towards the center of the river at an inclination of about 1 in 40, to a level under the river, where the rails will be at a depth of 61.6 below Trinity high water mark.

With regard to the above, it may no doubt be said that it is as yet only a matter of estimate; and though given by an engineer of standing, and approved by Parliamentary committees—one of whose special duties it is to investigate the estimates, for the purpose of testifying to their sufficiency—yet the estimates might prove fallacious. I now, therefore, proceed to give the cost of an important work at Chicago, completed some time since, and in many respects analogous to the one of which I am treating, but beset with some difficulty not to be encountered in passing under the Mersey, arising in great measure from the more uncertain material through which the heading had to be driven; that at Chicago being clay, and that at Liverpool red sandstone—the one being driven for two miles, or 3,520 yards, under Lake Michigan, the other only 1,300 yards under the river Mersey.

The Chicago tunnel was made by Mr. Cheeseborough, C. E., engineer to the municipality of Chicago, for the purpose of obtaining a more ample supply of pure water for the inhabitants of that important city, from a point beyond the reach of sewage contamination; hence its great length.

This work, embracing as it does two miles of heading, carried through clay, lined with two rings of brick-work, including a sum of $120,000 expended on the two shafts and the appliances connected therewith, cost $380,000, or £76,000.

The above amount spread over the 3,520 lineal yards of heading, gives £21 11s. as the cost of each lineal yard, and deducting therefrom £7, the value of the additional excavation, centering and brick lining (not found necessary in tunnels in the red sandstone), it will bring the price per lineal yard to £14 11s., without taking into account the more than double value of labor at Chicago, which has unfortunately greatly augmented the outlay upon this work.

Now, £20,000 expended upon 1,300 lineal yards of heading under the Mersey, gives the price for each £15 5s., so that, in drawing a comparison between the two works, a greater sum has been taken in the estimate for the one than has been actually expended on the other, and this is assuming the price of labor to be the same in both instances, which, however, is by no means the case, that at Chicago being very high.

I may here allude to a very interesting and instructive work, also very analogous to that proposed under the Mersey, which has been carried to a satisfactory conclusion at Attock, on the Khyrabad Pass, in India.

It consists of a heading 600 yards long, 6 ft. sq., driven under the river Indus, through a rock which forms its bed, at a depth of somewhat over 90 ft. below the surface of the flood water.

It has been carried on by a few laborers, under the charge of Mr. Robinson, who have succeeded in filling up the fissures they met with during the operation by simple "feather" wedging of wood, and have, by this expedient, been able to keep back all the water which otherwise would have flowed into the heading with a force due to the whole superincumbent column.

The cost of this work has been about £13,000, and spreading the whole outlay over the 600 yards, brings out the cost to about £21 14s. per yard, which goes to prove that had the labor expended upon it been paid for only at English prices, it would have been executed at a considerably smaller cost than that arrived at by estimate for making the heading under the Mersey.

I have lately constructed a water level nearly one-third of a mile long, through harder rock, yet far less compact and more broken up, having much larger feeders of water than any to be expected in the red sandstone. In driving this heading and the shafts connected therewith, single feeders were met with yielding 1,000,000 gallons per diem, yet these were dealt with without serious difficulty or expense, the cost not having been one-half that estimated for the Mersey work.

In driving the heading a boring-rod would, as is usual in water-bearing strata, be kept ahead of, and at the top of, the work, and thus due notice would at once be given of any unusual feeder of water, should such exist.

All ordinary cracks in the sandstone are readily made water-tight by the use of a "feather" wedge of timber tightly driven into them. If a large crack were met with, containing water (a most unlikely thing, as has been already shown), a lining of iron would be put into the heading, and pushed forward as the excavation proceeded, until the fault was passed.

The heading will be circular, and six feet in diameter.* It will, when completed, be available not only for draining the tunnels, but for telegraphic purposes, and probably also for conveying water from the Welsh lakes to Liverpool, thus avoiding a lengthened *détour* and most expensive works.

The heading having been successfully driven, I am confident that there will be no difficulty in letting a contract for a double line of railway under the river Mersey for £100,000, which would, indeed, give a price of £77 per lineal yard of tunnel—the work being through good hard sandstone, and thoroughly drained by means of the heading; whereas, £60 a lineal yard is a large price for tunnels, even through clay, where, of course, heavy lining, including an invert, is required.

The river tunnel being completed, the remaining works necessary to bring the two towns of Liverpool and Birkenhead into complete communication with each other will be of a very ordinary kind, and free from any unusual contingency.

Under the existing Parliamentary powers, the railway can be completed in a direct line from Church st., Liverpool, to Woodside, Birkenhead, with an intermediate station at the bottom of James st., and by its means, and by trains running every few minutes, passengers will be conveyed between the termini in six minutes. The authorized line runs entirely either under the river or under streets, and not a single house will be taken for the railway itself, and only one or two for station purposes. The railway can be readily constructed without interference with the traffic of the streets. The main line will be double, with extensive sidings for goods, in direct communication with the dock lines on either side of the river.

Surveys have been completed of extensions, whereby the Mersey Railway can be made to form a direct connecting link between the important railway systems on either side of the river, and this at a moderate expense, and with the destruction of hardly any property.

The effect produced by the opening of this railway will be very great. The docks of Liverpool and Birkenhead, now under the same management, form the noblest emporium of trade in the world, but their joint usefulness is much impaired by the want of satisfactory communication between the two sides of the river; and the immense resources of Birkenhead, developed at a cost of £7,000,000 sterling for docks alone, are lying comparatively idle, whilst the quays and docks on the Liverpool side are flooded

* See Plate. It is unnecessary to give any detailed description of the Plate, as it explains itself.

with a trade increasing daily, and already over-tasking their capabilities.

More dock and quay accommodation must be found. On the Liverpool side, to construct fresh docks, either north or south, is to place them miles away from the center of trade—at the north, in a very exposed situation, almost unapproachable in heavy weather; at the south, only available for vessels of comparatively small draught—what then so natural as to utilize the expenditure at Birkenhead, now yielding but a nominal return, but which, with the Mersey Railway completed, would be placed in a very different position. The Birkenhead docks and warehouses would then, as regards both passengers and goods, be placed within a few minutes, in all weathers, of the heart of Liverpool.

The immense traffic to be expected under such altered circumstances may be inferred from the fact that with the present imperfect means of communication, often brought almost to a standstill by a fog or a gale of wind, twenty millions of passengers, at least, pass over the ferries annually.

The Cheshire side of the Mersey abounds with pleasure sites for residential purposes, and not only New Brighton, but many other places would experience an immediate increase if railway communication were established. Thousands of persons who would prefer a residence on that side, are at present deterred by the difficulties of the daily crossing to their places of business.

The construction of this railway and its extensions, would also place Liverpool in direct communication with North Wales and Holyhead.

Liverpool, Birkenhead, and their surroundings now contain at least seven hundred thousand inhabitants, and the steady increase of population renders means of communication every day more urgent.

If this railway be not soon completed, an immense expenditure must be incurred to improve the approaches to the landing stages, which will, after all, not get rid of the most serious inconveniences connected with the ferries, which are chiefly caused by fogs and storms.

Those who have interested themselves in the Mersey Railway are in earnest in the matter, and if they meet with but moderate assistance from those locally concerned, Liverpool and Birkenhead will soon be connected by a direct railway.

THE DYER COURT OF INQUIRY.

The Court convened last November to investigate the official conduct of Gen. Dyer, has made its report to the Secretary of War. The investigation extended over a vast amount of details, and was exhaustive on those points in respect to which the accused had been condemned by the Congressional Investigating Committee. All possible latitude was given to the accusors in the matter of evidence, they being allowed to produce both oral and documentary evidence, and permitted to appear and to be represented by counsel. Several of them were heard as witnesses in support of the allegations, and "it is believed that no evidence offered has been excluded, which could possibly have shed any light upon the questions involved, or which would have affected the decision of the Court." The high character of the members composing it, viz., Gen. George H. Thomas, President, and Generals Terry and Hancock, members, and Gen. Joseph Holt, Judge Advocate, makes the decision unquestionable, and will settle all doubts in the minds of unprejudiced readers. The Court acquits Gen. Dyer of all the charges against him. The charge of receiving a royalty for the purchase of Absterdam projectiles was not sustained by the Court, its only foundation being a remark made by Gen. Dyer, to the effect that if anybody was entitled to a royalty, he himself was. The Court say that "the remark, if ever made by Gen. Dyer, was made to Mr. and Mrs. Dickson, *some time after* the only order ever given by him to Dickson & Lane had been issued. [This order was only partially filled.] The whole conduct of Gen. Dyer in reference to this contract and the payments thereon seems to negative the idea that he had a corrupt motive in giving the contract, or became in any manner interested in it. The evidence as to Gen. Dyer's assertion in the matter of royalty, was either the pride of an inventor, or a desire to protect the interests of the United States. It is established by the testimony that he always held the opinion that the Government should, of right, have the privilege of using, free of charge, any invention that might be made by an officer in the public service, and that he had acted upon this principle when, in 1861, the temptation was presented of a large sum offered to him for a patent right, to be taken out by him on a shell of which he seems to have claimed the invention, to be then transferred to other parties. He declined to do so, alleging that if the invention was of any value, the use of it belonged to the Government, and "there was not money enough in the country to buy it of him."

With reference to the charge that the displacement of Gen. Ramsay, and the appointment of Gen. Dyer had been procured by an intrigue, in which officers of the Ordnance Department were concerned, the Court finds from the evidence, and especially from the testimony of Secretary Stanton and Asst. Secretary Watson, that it is without foundation. "Mr. Stanton stated that Gen. Dyer never solicited the position from him, but 'that he ordered it of his own notion,' and that he does not think that any human being knew of his determination to appoint Gen. Dyer, until after he had concluded to recommend him to the President, except himself and Assist. Secretary Watson." Mr. Watson testified that the President told him "that he had concluded to nominate Gen. Dyer to the position, not upon any political or personal consideration, but solely with reference to his professional merit, and the requirements of the service."

The findings of the Court are equally explicit upon the other points charged, and the whole country will not only congratulate Gen. Dyer upon the triumphant vindication which his own conduct has received, but will congratulate itself also upon finding such integrity in one of its most responsible public servants. D.

MINING NOTES.

From the "Quarterly Journal of Science."

The project for organizing a Colliery Insurance Company, to embrace a provision for the survivors of those killed in colliery accidents, and to reimburse the colliery proprietor or worker for any loss accruing to his property, is again exciting attention. A letter has been published by Mr. Stephen Sleigh, of Austin Friars, which clearly shows the practicability of such a system of insurance. We learn from this letter that the value of the colliery property of Great Britain is estimated at £70,000,000 sterling. The production of coal is at present 104,000,000 tons per annum, and in obtaining this, on the average of ten years, 1,000 lives are lost in each year. It appears that two pence per week per man would produce a fund from which £100 could be given to widows and children of the deceased collier, and that a very small premium, varying of course with the district, would secure the insurer from any serious loss to his property. As active measures are about to be taken to establish this most important principle, we content ourselves at present by directing attention to the movement.

Coal in the Colorado district is a matter of great importance. According to the "Denver News," General Pierce stated to the Board of Trade that besides the bed of 31 in., discovered near Fort Supton, on the Platte, there were also two beds on the Cache-la-Poudre. One of these beds was 4 ft. thick, and the other about 18 in. The "Salina Herald" says that in digging a well on the east side of the Smoky Hill River—less than two miles from town—a bed of good bituminous coal, 18 in. thick and about 20 ft. below the surface, was cut through.

Coal mining in France has, during the past year, been particularly active. This will be seen from the following statement of the production during each of the last six years:

	Tons (statute).		Tons (statute).
1863	10,516,752	1866	11,807,142
1864	11,001,249	1867	11,975,164
1865	11,785,714	1868	12,345,000

The colliers of Belgium have not exhibited the same progressive increase. From the report of Mr. F. Iocham, Director of Mines in the Province of Hainault (which is the last published authority on the production of coal in Belgium), we learn that to the end of 1867 the production was as follows:

	1865.	1866.	1867.
Hainault	9,206,058	9,831,424	9,595,280
Namur.........	305,754	358,687	389,586
Liége..........	2,328,911	2,564,551	2,770,956
Total of the kingdom in metrical tons......	11,840,723	12,754,662	12,755,822

The copper mines of Africa have of late years been attracting considerable attention. The copper lodes in the Insiziva Mountain, about twelve miles from the southern boundary of Natal, are remarkable. Some comparatively small workings have been carried on about 80 miles from Port St. John. The deposit here is described as about 18 ft. thick by $2\frac{1}{2}$ ft. in depth. From this description it is evidently not a *vein* but a *bed*. This is clearly in a state of decomposition, since it is said that ore is replaced by a yellow ocherous deposit (*gossan* of miners) containing nodules of very pure carbonate of copper or malachite, varying in size from a pea to masses of 10 or 15 lb. weight. Some miners from D'Urban penetrated deeper into the mountain, and again found a similar deposit. Portions of considerable masses have been found to contain as much as 56 per cent of metal, the average, however, being from 30 to 40 per cent. Silver was found to the extent of 5.30 ounces to the ton of copper, and a trace of gold was detected.

Chromium is stated to have been discovered in large quantities in Maryland and Pennsylvania. Chromate of iron, of fine quality has also been found in Victoria. We understand samples of this mineral and antimonial ores, of good quality, have been shipped to this country with a view to determining their real commercial value.

In a cave in the mountain of Galenstock, which it is well known separates the cantons of Berne and Urich, a valuable deposit of topaz has been recently found.

Tin mines in Siam are, on the authority of the "Journal of the Society of Arts," about to be worked. We quote the paragraph:

"Another tin district is about to be opened at the Isthmus of Kra. The immense value of the tin workings at Junk, Ceylon, or Phuket, supposed to be not less than 150,000 tons per annum, has incited a Chinese merchant to propose the active development of the Kra mines, and as tin is supposed to abound along the whole range of the Malay peninsula, there are many who believe in his success. He is to have the government of the district to enable him to carry out his designs. The river of Kra is the southern boundary between British Burmah and Siam."

Seeing that the annual production of tin is as follows:

	Tons.
England	7,296
Banca	4,260
Billeton	1,900
Other parts	3,000
Total	16,456

—the 150,000 tons said to be produced at Junk is an evident absurdity. During the past year the Chinese merchants have been the largest buyers of British and Dutch tin, to which circumstance we owe the rapid rise in the price of tin which has lately taken place. This proves that they have not any great expectation of very considerable production of this valuable metal nearer home.

The prominence which has been given to technical education has led to a proposal to found a Professorship of Mining in the University of Glasgow; and a deputation has been in communication with Professors Ramsay and Huxley, of the Royal School of Mines, on the question of establishing a mining school in Wales. The experiments made already in Glasgow, at Bristol, and by Sir Charles Lemon, and others, in Cornwall, should teach the lesson that it is quite impossible for the miner to attend any fixed central school. The only practical and useful system of imparting instructions to the miners is that—adopted with great success by the Miners' Association of Cornwall and Devonshire, and by Mr. Dagliesh, in the neighborhood of Seaham — of sending the teacher to the miner, and giving him the advantages of a school of mines in the very midst of the district in which he labors.

GOLD.—The Nova Scotia gold fields have produced during the past three years as follows:

	Ounces.
1866	25,204
1867	27,314
1868	20,733

The production of the quartz rocks of Merionethshire has fallen to 490 ounces in the period between October 1st, 1867, and December 31st, 1868.

There has been a small rush to certain gold fields in Sutherlandshire. On a district not far from Helmsdale, which was known only to a few sportsmen and shepherds, recognized as the Kildonan Burn, a regular system of "diggings" has been organized, and the burn has been christened as "Gold Creek." The results are not, however, satisfactory, since it appears that the most industrious gold-seeker cannot realize more than five shillings a day.

THE HEATON PROCESS.—Considerable differences of opinion still prevail as to the value of the Heaton steel-making process noticed in our last number. We have carefully read and considered all that has been said in favor of the process, and against it. We are not by any means satisfied with the tone which has been assumed by those who have entered on the discussion of the question. Indeed, it is to be regretted that many of the statements which have been copied from paper to paper should ever have been made at all. They are obviously not consistent with our knowledge of the chemical changes effected in a mass of iron when subjected to the action of nitrate of soda. We have been informed by one of the largest of the Sheffield steel manufacturers, that, while he waits to see the result of a continuance of the experiments carried on at Langley Mills, before he adopts it, he is strongly predisposed in favor of the process; that he regards it hopefully, and, we are bound to say it, that he is greatly pleased with the liberality and openness observed by Mr. Heaton. With these remarks, which we introduce mainly to convince our readers that we are not inattentive to the experiments in question, we leave the Heaton steel process until its more complete development removes it from the doubful position in which it has been placed by injudicious advocacy.

A discussion of some interest in connection with the Heaton process has been opened in the pages of "The Chemical News." It arises out of a paper read before the Chemical Society, by Dr. B. H. Paul, on "The connection between the Mechanical Properties of Malleable Iron and Steel, and the amount of Phosphorus they contain." Mr. W. Mattieu Williams, of the "John Brown & Co. Limited" Works, Sheffield, argues that Dr. Paul has shown an imperfect knowledge of his subject. That although Dr. Paul's conclusion that 0.50 per ct. does not impair the quality of steel, is correct when it applies "*to tenacity as measured by a direct and gradually applied longitudinal or axial strain*," yet that it is absolutely wrong when it is made to refer to steel which is to be employed for cutting instruments of any kind. "It is obvious that the power of resisting a sudden, a vibratory, and a transverse shock is the property most demanded," and that here the smallest quantity of phosphorous is highly injurious; "this is just the property which phosphorus tends to destroy."—*Quarterly Journal of Science.*

COMMUNICATION BETWEEN PASSENGERS AND GUARDS.—Under the provisions of an Act of Parliament, passed last session, all trains running distances of twenty miles or more, without stopping, must, after April, 1869, be supplied with some sufficient means of intercommunication between passengers and guards. With a view to test the different means for accomplishing this object, some experimental trips were undertaken on the line between York and Scarborough, at the latter end of November last, and on the London, Chatham and Dover Railway, between London and Seven Oaks, during the following week. Three systems have been proposed for the purpose, viz: 1. The rope pulls, which is the oldest of them all. 2. The electrical signalling system, of which there are many varieties, and some of them have already been in use for a length of time on the various lines of railways; and, 3. The pneumatic system, which, whilst it is the newest, is also in many respects the most efficient. Space will not admit of our giving a detailed description of the several systems that were submitted to trial. The principle of the rope and electric bell system will probably be well known to most of our readers, and we shall not therefore make further reference to them here. The pneumatic system, being novel, may, however, claim a brief notice. The signaling apparatus consists of a heavy gong upon the engine or tender, and a smaller one in the guard's van. Both these gongs are struck by hammers, which receive direct motion from the train when a signal is given. When no signal is passed from passengers or others, these hammers are kept away from the gongs, and they are put into gear in the following manner. A tube runs along the whole train, beginning at a pump in the tender, passing from carriage to carriage, and ending in a plug at the back of the train. This pipe, which is worked by the machine, keeps pumping the air out of the pump, and sustains in it a partial vacuum. Underneath those vehicles, which are supplied with gongs, there are shallow cylinders in connection with the vacuum tube, from which, the air being exhausted, their pistons are drawn backwards, and pull thereby the striking portions of the bells out of gear. Over each compartment a T-piece is inserted in the tube, and a plug is fitted into its lower stem so as to keep the tube air-tight. The passengers give signals by pulling out these plugs, and this, breaking the vacuum, causes the bells to fall into gear.

That the pneumatic principle possesses many advantages over the other two, both as to certainty of action and from its non-liability to be tampered with, is beyond a doubt; but the committee of Railway Managers have nevertheless recommended the rope system, probably on account of its cheapness, and their recommendations have been accepted by the Board of Trade.—*Quarterly Journal of Science.*

PAPERS ON CONSTRUCTION.

No. II.

By Lieut. C. E. DUTTON.

(Continued from page 311)

13. Resuming the expression derived, Sec. 9, from the consideration of the resistance of a cross section to rupture by a transverse force, viz: $\frac{s\,b}{x}\int x^2\,d\,x$, and noting that the resistance to compression is equal to that to extension, so that the expression becomes $\frac{2\,s\,b}{x}\int x^2\,d\,x$, and substituting $d = 2\,x$, and integrating

$$R = \frac{2\,s\,b}{x}\int x^2\,d\,x = \frac{1}{6}\,s\,b\,d^2,$$ and the moment of inertia $M = \frac{1}{12}s\,b\,d^3$.

These equations are founded upon the assumption that the beam has a symmetrical section with reference to the neutral axis. In cases where the cross section is otherwise, the position of the neutral axis remains to be determined. Since the moments on both sides of this axis, whatever its situation, must be equal and opposite, this axis must pass through the center of gravity, for no other condition will satisfy such an equation of moments. The only obvious method of determining such a case seems to be to resolve the cross section into a number of geometrical figures, the positions of whose centers of gravity with reference to the center of gravity of the whole mass may be readily determined, and thus find the moment of inertia of each component figure with reference to the neutral axis of the section. The whole moment will be equal to the sum of the moments of the components, and the moment of any component is equal to the moment of its area with reference to its own neutral axis, added to the product of its area into the square of the distance between its own center of gravity and that of the whole section. Let $A' =$ the area of a subdivision, m' its moment of inertia with reference to its own neutral axis, and x' the vertical distance between its center of gravity and that of the section; then the moment of the whole section

$$M = \Sigma . m' + \Sigma\,A'\,x'^2.$$

The following example is given by Prof. Rankine for calculating the strength of the Hodgkinson beam. It is assumed to give way by the tearing of the lower flange. The following are the dimensions:

	Area.	Depth.
Upper flange,	A'	h'
Vertical web,	A''	h''
Lower flange,	A'''	h'''

Total, $A'+A''+A''' = A$, $h'+h''+h''' = h$.

The determination of the position of the center of gravity will show the distance of the neutral axis above the bottom to be

$$x' = \frac{h}{2} - \frac{(h''+h''')A''' - (h'+h'')A' - (h'''-h')\,A'}{2\,A}'$$

and the moment of inertia of the section

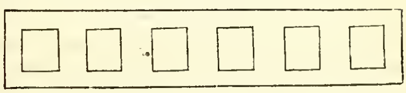
$$M = \frac{A'h'^2 + A'' + h''^2 + A'''h'''^2}{12} + \frac{1}{4\,A}\ \{A' A'''(h'+h'''+2\,h'')^2 + A'A''(h'+h^2)^2 + A''A''' (h''+h''')^2\},$$

and the moment of resistance

$$M' = \frac{S\,M}{x'}.$$

14. The formulæ of transverse strength thus deduced are in conformity with those obtained by the best authorities on this subject. Mr. W. H. Barlow, however, has shown conclusively that there enters into the strength of beams another factor not hitherto discussed, and which is dependent on the resistance of the beam to flexure. It was found in the case of cast iron beams that the calculated force was less than half the force actually necessary to rupture the outer fibers of a beam, and in speculating upon the cause he was led to think it probable that the effect of the lateral action of the fibers or particles of a beam, or the cohesion of successive laminæ, constituted a resistance to flexure. To test this theory, which assumes that there is a resistance independent of direct tensile and compressive resistance, and varying as the deflection, there were cast a number of girders with rectangular openings (like Fig. V), all having the same sectional area in the upper and lower ribs, but the distances varying between them. In these girders the neutral axis would necessarily be in the center, and the circumstances of rupture would be the same in all except with respect to flexure.

FIG. V.



Let $a =$ the united area of the upper and lower ribs, a' the area of the intervening space, d the total depth, c the distance between the upper and lower ribs, l the length of bearing, W the breaking weight, and F the force required to produce rupture in the extreme outer particles or fibers. Then $a + a' =$ the total area of section, and $W = \frac{2\,d\,F}{3\,l}(a + a') - \frac{2\,c\,a'}{3\,l}\frac{c\,F}{d}$; $= \frac{2\,F}{3\,l}\left\{(a + a')\,d - \frac{a'\,c^2}{d}\right\} = \frac{2\,F\,a}{3\,l}\left(d + c + \frac{c\,2}{d}\right)$ and hence the value of F becomes

$F = \frac{3\,l\,W}{2\,a\,(d + c + \frac{c}{d}{}^2)}$, and if the strength depended only on the direct tensile strength, F ought to be constant and equal to the direct tensile resistance of the material, which in the beam used was about 18,750 lbs. It was found, however, when the beams were subjected to breaking weight that the value of F was much greater, and showed a close relation to, and probable dependence upon the amount of deflection. Other experiments upon solid beams gave similar results. Finally, a series of experiments was made upon beams having the same total depths, but with variable depths in the openings. These beams would have nearly the same amount of deflection when subjected to a breaking weight. They showed very conclusively that when the deflection is the same the resistance increases where the depth of metal in the beam is increased.

These experiments then elicited the following facts as regards beams formed of parallel bars, separated at given intervals by vertical ribs.

1st. That in every case the resistance, or the value of F, is greater than that due to the tensile strength of the metal.

2d. That with the same depth of metal in the beams, and the same bearing, the resistance is greater when the deflection is greater.

3d. That with the same deflection and the same length of bearing, the resistance is greater when the depth of metal is greater.

It follows then that there is an element of strength depending on the amount of deflection in connection with the depth of metal in the beam, or, in other words, dependent upon the degree of flexure.

Now, if from the value of F the tensile strength of the metal is deducted, it will be found that the remainder maintains nearly a constant ratio in each case to the depth of the metal multiplied by its deflection. It would appear then that F is composed of two factors, one constant and depending upon the resistance to direct tension, the other varying directly as the degree of flexure.

Let $\phi =$ the resistance to flexure in a solid beam at the time of rupture, $D =$ the depth, $d =$ the deflection, $f =$ the tensile resistance, and $F =$ the total resistance. Then in a solid beam $F = f + \phi$. Also let F', d' and D' represent the total resistance, deflection and depth, of a beam with an open section; then the resistance arising from lateral action varies as the depth into the deflection, and

$$F' = f + \phi\,\frac{D'\,d'}{D\,d} \quad . \quad . \quad . \quad (1)$$

The value of ϕ may be determined from this equation in two ways, first by supposing f to be a constant quantity, and, secondly, by supposing f and ϕ to have a constant ratio. Adopting the second mode, let 1 to m represent the ratio of f to ϕ, then, $f = m\,\phi$, and $m\,\phi + \phi\,\frac{D'\,d'}{D\,d} = F'$, or

$$\phi = \frac{F'}{m + \frac{D'\,d'}{D\,d}} \quad . \quad . \quad . \quad . \quad (2)$$

which ought to be a constant quantity in all experiments. The forms of beam employed in the experiments were of two kinds, solid rectangular bars and open beams or girders, both of cast iron. The value of F in one solid beam was found to be 41,709 lbs., and the value of f, from experiments on direct tension, 18,750 lbs., leaving 22,959 as the value of ϕ, so that the ratio of ϕ to f was about 1.00 to .81. The mean of a considerable number of experiments gave the mean ratio as 1 to $\frac{4}{5}$.

These results, though not exhibiting complete regularity, were sufficiently uniform to indicate that the assumed law of the variation of this resistance is a close approximation to the truth. In equation $2\,\frac{D'\,d'}{D\,d}$ represents the ratio of the depth of metal in each beam multiplied by its deflection to the depth of metal in the solid beam multiplied by its deflection. But the deflections, as might have been expected from known laws, were nearly in the inverse ratio of the total depths of each girder, therefore the degree of flexure, and consequently the resistance to flexure in each will be nearly as the depth of the metal, divided by the total depth of the girder, and we are thus enabled to obtain a formula for computing approximately the breaking weights of these girders without first ascertaining their deflections. Thus, if $a f$ be the resistance due to tension, and $a \cdot \frac{\phi D}{d}$ be the resistance due to resistance to flexure, then $W = a \left(f + \frac{\phi D}{d}\right)$ will be the united effect of the two resistances.

The following are the properties arising from this resistance to flexure:

1st. It is a resistance acting in addition to the direct extension and compression.

2d. It is evenly distributed over the surface, and consequently (within the limits of its operation) its points of action will be at the center of gravity of the half sections.

3d. This uniform resistance is due to the lateral cohesion of the adjacent surfaces of the fibers or particles, and to the elastic reaction which thus ensues between the portions of a beam unequally strained.

4th. It is proportional to and varies with the inequality of strain between the fibers or particles nearest the neutral axis, and those most remote.

15. Taking the equation of the moment of resistance of a cross section, and putting it in the form $2\, s\, b \int \frac{x}{d}\, x\, d\, x$, and in the place of $\frac{s x}{d}$ substituting $\frac{f x}{d} + \phi$, we have

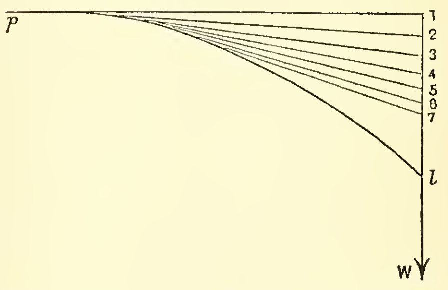
$$M = 2\, b \int \left(\frac{f x}{d} - \phi\right) x\, d\, x.$$

Integrating this between $x = \frac{1}{2}\, d$, and $x = o$, we have the formula $M = \frac{1}{2}\left(\frac{1}{3} f + \frac{1}{2}\phi\right) b\, d^2$. If, in the various expressions of the strength of cross sections of variable form, in the place of $\frac{1}{6}\, s$, we substitute the coefficient $\frac{1}{2}\left(\frac{1}{3} f + \frac{1}{2}\phi\right)$, we shall have corrected formulas for this new element of resistance, and much nearer the truth than those just given. The value of ϕ may be deduced for any weight from equation 2. The foregoing results having been obtained experimentally from cast iron beams, it might have been apprehended that the same would not hold good for wrought iron. The existence, however of a similar law in the case of wrought iron beams was practically demonstrated. But the relative values of f and ϕ are not so readily ascertained, because the material yields by crushing and not by fracture. Another point requires consideration, viz: that the ultimate compressive strength of wrought iron is but little more than half its tensile strength, while in cast iron the compressive is six times the tensile strength. But in wrought iron the force required to overcome the *elasticity* of the material is nearly the same in compression and extension; the difference being that the force which overcomes the elasticity, when applied as a compressive strain, distorts the material, while in tensile strain the elasticity may be overcome long before the material yields by absolute rupture.

16. *Deflection of Beams.*—Resuming the bent lever hypothesis, it will be seen that the effect of the weight at any given plane of cross section is a tendency to rotate that plane about a horizontal axis, perpendicular to the neutral axis. To a very small extent this rotation actually takes place, the amount of motion being limited by the elasticity of the material, or the degree to which the normal distances between two particles can be extended or shortened. The planes of cross section, therefore, cut each other at the neutral axis. The amount of curvature at any point will vary as the force applied, and that force is equal to the weight multiplied by the lever arm, or, more concisely, is equal to the moment of the weight.

Let $p\, l$ be a layer of a beam deflected by the weight W, and let x represent the distance of any point in it from l. Then the

FIG. VI.



angles $1\, p\, 2$, $2\, x'\, 3$, $3\, x''\, 4$, etc., will vary as the curvature of the beam between the points of tangency of $1\, P$ and $2\, x'$, of $2\, x'$ and $3\, x''$, of $3\, x''$ and $4\, x'''$, etc. This will become clear by referring to Fig. VI, where $P\, c\, x'$ represents the angle of rotation between the two contiguous surfaces made by a plane of cross section. Since, as a condition of tangency, $1\, p$ is perpendicular to $p\, c$, and $2\, x'$ perpendicular to $c\, x'$, the angle included by $1\, p$ and $2\, x'$ must always be equal to $p\, c\, x'$. Hence the angle included between two tangents will vary as the curvature, which varies as the moment of the weight. Again, with a given angle made by two tangents, the amount of divergence will vary as the length of the tangents, that is, the farther any two tangents are extended the more widely they will separate. But the length of a tangent for small deflections is equal to x, and the divergence between any two consecutive ones (denoted in Fig. VI by the spaces 1.2, 2.3, 3.4, etc.) is the differential deflection due to the curvature of the differential space $d\,x$. The deflexion $d\,D$ therefore will vary in the combined ratio of the angle, or $W\,x$, and the length of the tangent, *i. e.*, as $W x^2$. Finally, it will also vary as the length of $d\,x$, or as the number of particles separated or stretched by the force $W\,x$. Taking $m =$ an experimental constant, we deduce the equation

$$d\,D = m\,W x^2\,d\,x, \qquad (1)$$

$$\int d\,D = W\,m \int x^2\,dx, \qquad (2) \quad \text{and}$$

making $x = l$, we have $D = W\,m\,\frac{l^3}{3}$. This equation is true, however, only for very small deflections. But as small deflections are the only ones to be encountered practically, this will be found sufficiently near for practical purposes. The expression $W\,x$, which is the moment of the weight, is called the bending moment in treating of deflections.

17. When the beam is loaded uniformly the expression for the bending moment is altered. If the point x be taken as before, the bending force exerted at that point will be that due to the weight between x and the free end, and its moment, since it is uniformly distributed, is $\frac{W'\,x}{2}$. But obviously $W' = \frac{W\,x}{l}$ and hence the bending moment is $\frac{W\,x^2}{2\,l}$. Using this bending moment eq. (1) becomes

$$d\,D = \frac{m\,W x^3\,d\,x}{2\,l}, \qquad (3)$$

$$\int d\,D = \frac{W\,m}{2\,l} \int x^3\,d\,x, \qquad (4) \quad \text{and}$$

making $x = l$, we have

$$D = \tfrac{1}{8}\,W m\,l^3 \qquad (5)$$

When the beam is supported at both ends, and weighted in the middle, we may without error consider it as supported in the middle, and weighted at each end with one half the weight, in which case $x = \frac{l}{2}$ and equation (2) becomes

$$\int d\,D = \tfrac{1}{2}\,W\,m \int x^2\,d\,x = \frac{1}{48}\,W\,m\,l^3, \quad (6)$$

When the load is uniformly distributed over the whole length, then by referring to Sec. 7 it will be seen that the moment of weight, or bending moment, becomes $\frac{W\,x\,(l-x)}{2\,l}$. Substituting this for $W\,x$, in equation (1), we have

$$d\,D = \frac{m\,W\,x^2\,(l-x)\,d\,x}{2\,l} \qquad (6) \quad \text{and}$$

$$\int d\,D = \frac{m W}{2\,l} \int l\,x^2\,d\,x - \frac{m W}{2\,l} \int x^3\,d\,x \qquad (7)$$

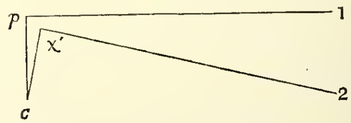
making $x = \frac{1}{2}\,l$ the expression, reduces to

$$D = \tfrac{5}{384}\,W\,m\,l^3 \qquad (8).$$

Since the deflection is usually expressed in inches, it is advisable in assigning numerical values to l, to reduce the measurements to inches, so that $W\,l$, or the bending moment, always express "inch pounds," and thus leave the unit of measurement for deflection in its simplest form.

18. Thus far we have treated of the deflection only, in its relation to the length and weight of the beam, and have practically assumed the cross section of the beam to be a fixed quantity. It is now necessary to treat of the relations of the bending moment and deflection to the cross section. In the foregoing equations the constant m is intended to be a factor expressing the deflection of a beam of a given length, and cross section under a given weight, while the whole equation gives the deflection of a beam of the same cross section, but of variable length. When the cross section is variable, m is no longer constant. But it still holds a determinable relation to the breadth, depth, and modulus of elasticity, which can be expressed in terms of those quantities. Assuming, then, that m represents the deflection of a beam of given length, but variable depth, its bending moment, $W\,l$, will vary inversely as the moment of resistance of the cross section, that is, as $\frac{1}{6}\,s\,b\,d^2$. By referring to Fig. VII it

FIG. VII.



will be seen that the angle formed at the neutral axis, by the elastic yielding of two contiguous particles, will vary directly as the bending moment, and inversely as the modulus of elasticity and the moment of resistance of the cross section. But the tension on the fiber $p\,x'$ remaining the same, the angle $p\ c\ x'$ will vary as $p\ c$, or as $\frac{1}{2}\ d$. Hence the depth again enters the expression, which now becomes $m = \frac{12}{E\ s\ b\ d^3}$. But since $\frac{1}{12}\ s\ b\ d^3$ is the moment of inertia of the cross section, we may write

$$m = \frac{1}{E\ I} \qquad (1)$$

E represents the modulus of elasticity with respect either to compression or extension. Taking the equations of the preceding section and substituting this value of m we obtain general expressions for loads variously distributed.

One end fixed and loaded at the other . . . $D = \frac{W\ l^3}{3\ E\ I}$ (2)

One end fixed and uniformly loaded . . $D = \frac{W\ l^3}{8\ E\ I}$ (3)

Both ends supported and loaded in the middle, $D = \frac{W\ l^3}{48\ E\ I}$ (4)

Both ends supported and uniformly loaded . $D = \frac{5\ W\ l^3}{384\ E\ I}$ (5)

(To be continued.)

IMPROVEMENTS IN COAL GETTING.

Compiled from "The Practical Mechanic's Journal."

That which has more than anything else characterized the mechanical progress of our own times, the steady and increasing substitution of machine agency for human and animal labor, has not until within a very few years made much advance in the underground workings of the coal-pit. Some grand ameliorations have been made, but much remains to be done; and so surely as the sewing machine was the true remedy for the miseries shadowed in the "Song of the Shirt," so must the effectual removal of the remaining ills of coal-pit labor (and of all other labor of analogous character) be found not so much in legislation as in the invention of effective methods for superseding it.

There have been other sufferings in coal-pit labor besides human ones. Horses are still largely employed in drawing the "corves" of coal from the headings to the bottom of the "drawing shaft." Without being sentimental, it may be boldly said that few animal existences can be more unnatural or unhappy than that of the coal-pit horse. But the increased depth of workings, the extension of underground "inclines," and many other circumstances, all converging towards the question of "cost," have sharpened the wits of coal viewers and engineers; and already vast progress has been made in the north of England and elsewhere, in substituting steam-power haulage underground, by means of the "endless rope system," for horse labor. Thus, not universally, but within certain limits, we see the curious succession of women and girls as beasts of burden giving way to boys and men, these to "ponies," and the last to steam. Several years have elapsed since the earliest attempts were made in Northumberland and Durham to apply mechanical haulage by one of the four systems under which it is at present worked, viz., by that of the single tail rope; and at least five years ago we ourselves witnessed, in the Hetton collieries, the degree of perfection to which that plan had even then been brought under the skillful superintendence of the viewer, Mr. J. Daglish, M. E.

The three other systems now all in use are, the endless chain system, the endless rope system—of which there are two modifications, not reckoning as a distinct system the endless chain plan of South Wales—and the system of single rope planes. In all of these the full corves are seized by the rope or chain at the required point, dropped off free, either by detachment or by cessation of the power at the required points, and the empty corves are brought back by power. A boy is needed to each train, and, as at Hetton, the highest ingenuity has been exhibited in devisal of the methods by which detachment from a constantly running rope is provided for. To the honor of mother wit be it recorded, that the beautifully simple and effective, though most original and ingenious, form of detaching hook in use at Hetton, was invented by one of these untaught boys who guided the trains of corves.

An admirable account of what has been done up to this time in the way of steam underground haulage, may be found in the "Transactions of the North of England Mining Institute," volume xvii, page 7, for August, 1868, with very carefully tabulated experiments as to the cost of such haulage work. According to circumstances, and chiefly to the rate of inclination of the trams, and the amount of coal hauled per twelve hours, it varies from a little above a penny per ton per mile, to nearly fourpence per ton per mile, of coal drawn. To these able reports we refer our readers, for our direct object here is not with the methods of leading the coal when "got" underground, but with improvements in the means of getting it.

The methods employed up to the present hour for "getting"—*i. e.*, for detaching coal from its bed, as generally practised in Great Britain—may be said to consist in "holing," under-cutting, or over cutting (generally comprised under the term hewing), the coal by hand labor; to a limited extent as yet, performing all these or at least two of them, by one form or other of "coal-cutting machinery;" wedging by hand to bring down the more or less isolated blocks of coal; and in many pits blasting the coal down or out of its seat, more or less by gunpowder or other explosive agents.

These methods are equally in use, whether the coal seams be worked by headings, by single or double "pillar and stall," or upon the "long wall" systems; and if we include in our view foreign collieries, more especially those of France, Belgium and Westphalia, where the seams are in general much more steeply inclined and disturbed than in Great Britain, these methods apply equally to all thick seams, however circumstanced. That blasting has been occasionally productive of accidents more or less serious, through the chance of the ignited fuze or the flash of the explosion igniting fire-damp, admits of no doubt. The absolute number of such accidents is small, and their proportion in relation to those traceable to all other causes is unquestionably small; but although that is so, it is the obvious dictate of prudence, if it be found practicable, to avoid blasting altogether, or in at least all "fiery seams." No wise manager can feel at ease in being obliged to sanction the continual use of blasting, where every charge, when exploded, may be, for ought that he or any one can predict to the contrary, in connection by an invisible and unknown gasiform fuze with the great explosive magazines of fire-damp that may be accumulated in the "goafs" or other parts of the workings. *Prima facie*, therefore, everything indicates the desirability, if possible, of getting rid of subterranean coal blasting, on the grounds of humanity and prudence.

But let us look at the matter a little more narrowly in the light of practical needs, etc. Drift-ways must be run into the coal, whether thick or thin, in order to reach and work the seam. These are often miles in length; unless in the exceptional cases of the very thickest seams, the headway required by the drift way, heading, or rolley way, which is from seven to nine feet, obliges more or less of the coal roof or coal seat, or of both, but generally of the first only, to be removed. This is very frequently composed of hard grit stone, or of "clunch," or other argillaceous or arenaceous material scarcely less hard. For the excavation of these primary works, in nearly every colliery, gunpowder, or some equivalent for it, is indispensable.

Again, there are certain coals which are themselves so hard that (as yet at least) no one has even suggested any way by which they can be dislodged from their beds but by means of blasting. Such is the case with much of the American anthracites, with some of those of the European Continent, and, above all, with the pure anthracite of the Kilkenny coal field in Ireland, which contains about 97 per cent of pure carbon, breaks with a vitreo-conchoidal fracture, and is almost as hard and difficult to dislodge as the rigid carboniferous limestone in which the seams occur, and to the "roof and seat" of which the coal is obstinately adherent. There are, therefore, cases in which coal mining must, to the end of the chapter, be pursued by means of blasting, so that we have our views as to the substitution of some other means of dislodgment thus limited at least.

We ought not here to omit to remark, before going further, that there is a wide field open for experminents with other explosive agents than gunpowder, with a view to discover whether some may not be found, and be so exploded that their dislocating effects may be employed, and yet that any fuze at all, or any flash capable of igniting fire-damp, shall be avoided or abolished. As to the fuze, there is no longer the slightest practical difficulty or objection on the ground of expense, complication, trouble, delay, etc., in employing galvanic or rather magneto-electric fuzes; and as the igniting points of these are plunged in the midst of the charge, ignition of fire-damp is no longer possible from the fuze; it becomes then limited to any flash producible by the charge; but may not this, too, be wholly got rid of?

Gun-cotton, nitro-glycerine, dynamite, nitro-picric powder, all give less flash, and one probably less capable of producing ignition in surrounding gasses, than that of gunpowder, all being fired as usual. But a discovery very recently made in Mr. Abel's laboratory at Woolwich, and since, to some extent, worked out into a practicable form, has shown that the explosive effect of gun-cotton in a given charge may be prodigiously increased in intensity by firing the charge, not by mere ignition at all, but by ignition and a blow or violent vibratory jar at the same instant. The same thing is no doubt true, and *a fortiori*, of nitro-glycerine. It is thus, at this crude stage of the inquiry, plain that we have the means of employing explosive agents greatly more potent and less capable of spreading ignition to fire-damp than gunpowder, and that we can still further reduce the charges of these more potent explosives by employing a suitable method of firing them. We may thus reasonably hope to attain for any given use charges sufficient, yet so small that the mere cooling contact of the coal or rock split by them shall prevent even a very slender probability of the flash, if any, spreading beyond the hole, or reaching any point to ignite fire-damp.

Experimental researches to decide the scope and value of such an inquiry appear to us quite worthy of our most advancing and scientific colliery engineers, with the aid and countenance of the Northern or of the South Wales Mining Institutes. Still there remains this incontrovertible proposition, so well insisted upon recently by Prof. Warrington Smythe, that where there must ever remain more or less room for doubt as to danger, and that danger such as may imperil many human lives, the judgment of every prudent man ought to be, "get rid of explosives in coal mining altogether, if it can be done." Professor Smythe did not affirm that it could be done, nor do we believe that it can, in all cases. Beyond question the ablest and most successful attempts in this direction, as well as in that at the same time for relieving the heavy labor of the coal hewer, have been those of the contrivers of coal-cutting machines. These, in several forms — mainly divisible into two generic classes, viz., those which *hew* in the proper sense of the word, *i. e.*, chop away the coal by blows with a sharp-ended implement like a pick, driven by power; and those which *slice*, or rather grind away the coal by one or many advancing tools, slowly driven by power, and moved like the cutting tools of a slotting machine—have now been more or less under trial for nearly seven years, and in a few places, both in South Wales and in the North of England, have been (one or other) brought into successful use; the power employed being compressed air, supplied by a fixed engine above or underground, and the air led along by pipes to the faces of the headings, or to the wall faces in work.

What may be done by compressed air as a motive power we need not enlarge upon; it has been abundantly shown at the great Mont Cenis tunnel, of which we have given several notices in this journal. Now, besides the advantages effectuated by this class of machines (we have no intention of going into any critique as to their relative merits), of relieving the coal hewer of the very heaviest part of his labor, viz,, the "under-cutting" of the coal, and the owner of by far the greater portion of the coal wasted and destroyed by being reduced to powder by the under-cutting by hand, and limiting the "hewer's" task to the cross cutting of the blocks and "getting down," by whatever means, the masses of detached coal; there are these further advantages—that the "under-cutting" can be effected much more deeply in, from the "face," than is readily practicable with hand labor, and that when indispensable the coal bed may be "overcut," or freed from the roof, if need be, in the same manner—a thing nearly impossible with mere hand labor. It is, however, a very rare case indeed that any moderately heavy seam of "fat" or flaming coal, or any other but of the hardest anthracite, needs any over-cutting, and that, no matter at what inclination or dip of bed. It almost always occurs that if the coal be effectually under-cut, the mass, thus for several yards in length perhaps, and for a depth in, from the face, of from three to six feet, hanging in air free from its support below, only needs to be cross-cut or "holed," when it breaks off at the rear and from whatever slight attachment it may have had to the roof, and drops by its own weight, and then all that remains is to hew or part it into suitable-sized blocks, so as to load it into the "corves," and bring it to bank. This part of the work is done, partly by the blows of the pick, partly by the "hewer's bar," and in harder coal by driving in iron wedges.

Recently there have been some who have thought that wedging might be much more extensively used in coal mining; and that, in fact, by the application of a much more powerful form of machine-driven wedges, coal might be detached bodily from its bed without the use of blasting, without the use of coal-hewing machinery, or hewing in any form either for under-cutting or holing; and that, in fact, this one new class of tool, either the power-driven wedge, or, as its equivalent, the expansion of plungers by hydrodynamic pressure, should become almost the sole and sufficient resource of the collier. This is what we propose to submit here to some slight examination in the dispassionate light of the actualities of the problem sought to be solved.

Five mechanical arrangements for coal-splitting were recently brought before the Institution of Civil Engineers, three of them being principal, and the others only incidental to the discussion upon the original paper by Mr. S. P. Bidder, A.I. C E., "On Machines employed in Working and Breaking down Coal."

The machine of Mr. Bidder was described as consisting of a small hydraulic press of twelve tons power, to which was attached a pair of tension bars, bent in the form of a connecting-rod or hinge-strap. These were placed one over the other in the bore-hole, and between them, at the extreme end, there was a clearance box and two metal pressing blocks, between which was forced, by the action of the hydraulic press, a split wedge fifteen inches long, causing a lateral expansion of three inches. The ram was then withdrawn, and a second wedge was inserted between the two parts of the first wedge, and was forced up until sufficient expansion was obtained to break the coal. The operation could be repeated several times if found necessary. The whole apparatus would weigh about fifty pounds. The hydraulic press was in future to be made of steel, and the ram would be cored out. In practical working each gang of colliers would be provided with the tension bars and three wedges, while the presses would be under the charge of the men who at present occupied the position of firemen, so that no new class of labor would be introduced. Trials had been made both in the seven feet and the nine feet seams at Harecastle; and in the latter, with three wedges, about twelve tons of coal had been brought down in only three or four pieces. It was found that the press could be applied, and the blocks brought down, in less time than was consumed by firing and waiting for the smoke clearing.

The second described machine was by Mr. C. J. Chubb. He thought some more simple and practicable means of getting coal by mechanical power could be devised than the costly, but skilfully contrived, coal-cutting machines. His first idea was to apply wedges, acted upon by hydraulic force, but he was induced to abandon that system, owing to objections to the use of wedges, and to adopt instead an apparatus consisting of twelve plungers, set side by side in a steel bar, which plungers, when acted upon by water from a hydraulic pump, would separate the bar in which they were set from another bar, formed in the shape of a cover upon the plungers. The pressing apparatus was 25 inches long, and it was attached to a hydraulic pump by a tube two feet in length, so that it might be inserted into the coal to a depth of about 3 ft. 6 in. The apparatus, with the cover on, was $4\frac{5}{8}$ in. in diameter. When, by the action of the pump, the plungers had reached their limit of $2\frac{1}{4}$ in., and further expansion was needed, the plungers were readily brought back to their first position, by opening an escape cock for the water back into the partially vacuous close vessel out of which it had been pumped, when a liner could be inserted between the plunger and the cover; and this process could of course be repeated. In practice, however, it was found that the first expansion of $2\frac{1}{4}$ in. was more than sufficient. It was stated that the collective area of the plungers was 24 square inches, and as the pump could exert a pressure of twelve tons on the square inch, a total pressure of 288 tons could be brought to bear on the coal.

This apparatus had been tried in the South Wales district, where the coal was of the most varied description. It was observed that, by the present system of blasting, it occupied on an average two men ten hours to break down and fill into trams four to five tons of coal, of which twenty per cent was "small," and the remainder much shattered. On the other hand, with this apparatus two men could readily break down twenty tons in an hour, which could be filled, when loosened, at the rate of ten tons per man per day, the whole of the coal so obtained consisting of large solid pieces. Again, by the present system, in order to break down 500 tons of coal a day, from a "four-foot" seam, a "face" of 600 yards was required, whether as "pillar and stall," or as "long work;" whereas with this apparatus the same quantity could be worked from 300 yards of "face." In this way there would be less space requiring to be ventilated, the working operations could be concentrated, and facilities would be afforded for effecting economy in other respects. We may remark, in passing, that but very little stress can be laid upon these statistics. The amount of coal got per man per shift, or day, can scarcely be thus crudely stated with any certainty at all, and must vary enormously with circumstances; and while it seems here underrated, we must say the possible performance of the hydraulic coal-splitter seems both to want confirmation by actual trial, and in the absence of that to appear overrated.

The third contrivance was that of Mr. Grafton Jones, of Blaina Iron Works, Newport, Monmouth, and is also a hydraulic coal-splitter, differing from the former mainly in this—that Mr. Chubb's consists of a central tubular stem, carrying a long row of short plunger plugs along the length of its two opposite sides, like the suckers upon the tentacles of a cuttle-fish, which, being inserted into a 4 in. diameter, or thereabouts, jumper or auger hole, the plungers, by pumping in water, are forced out in opposite directions, and in direct contact with the coal. Mr. Chubb's is essentially the same in principle; but one range of plungers is suppressed, and the remaining range of these, in place of being forced out directly against the coal, is forced out against a sort of hollow, trough-shaped cast iron "liner," the interior of which fits the faces of the plungers, while the exterior fits the inside of the auger hole in the coal.

In the course of discussion it was incidentally mentioned that Mr. Joseph Bramah, the inventor of the hydraulic press, had proposed its use for coal-splitting; the form which he suggested having been simply that of an extremely strong bag of reduplicated leather, made waterproof. This in its flaccid state was inserted into the flat-shaped hole prepared for it in the coal, and water was then forced in until the distension of the bag caused the fracture of the coal in the direction of least resistance. The two other splitting methods brought before the institution we need but briefly allude to, as one of these merely placed on record an old device of one of the members for splitting rock or coal, etc., by means of a conical screw of steel, screwed into a split cylindrical wrought iron nut of considerable length, inserted into the bore hole; while the other was but a suggestion for diminishing the mechanical disadvantage of the oblique action of Mr. Bidder's wedges, by means which the talented suggester himself would probably, on more mature consideration, abandon.

Now, we must make bold to say that we entertain the most entire want of confidence in every one of these contrivances, as machines ever likely to be brought into practical use in coal mining; and we apprehend that every coal viewer or mining engineer, who possesses some actual experience in coal working, must come to the same conclusion. The proposition, in fact, common to all three contrivances is really this, that by means of large holes, four to six inches diameter, of a few feet in depth, bored somehow into the coal, in directions more or less parallel with the plane of the seam, and more or less diagonal to the working face, and by the insertion and use therein of these hydraulic driven wedges or plungers, it is practicable (in the working sense of that word), without any previous other work or preparation, to drive out the coal bodily, while still gripped firmly between its seat and the roof, and cause it to separate and fall in dislocated masses.

We shall not deny the possibility of doing this in some seams and in some cases, with nearly level beds of great thickness, and of just the best quality of coal for its successful application; but we do entirely disbelieve the practicability of so working the vast majority of coal seams in this or in any other country. Coal, whether thick or thin, deposited in water-saturated strata, to whose cavities, rugosities, and bendings it has been moulded beneath enormous pressure for ages in action, is everywhere obstinately gripped between roof and seat. When the seam is enormously thick, and most suitable in respect to hardness and softness and splitability (if we may coin such a word), it is barely possible that more or less of the coal might be thus forced out of its place, leaving, however, almost certainly in every case, more or less of it adherent to the roof and to the floor. But if the seam be but moderately thick (say four feet or under), if the coal be soft and friable, or if it be very hard and difficult to fracture; if the roof or the floor, or both, be of hard material; if either, or both, be uneven, and pitted at the "coal parting" with them—or if the coal join on direct to the floor or roof, or both, without any thin parting seam of vegetable charcoal, shale, or other very fissile material—then we feel pretty certain that such attempt to drag or push the coal out of its place, as it were by the neck, must end in complete discomfiture, so far as rapid and economical working are concerned, assuming that the physical possibility be conceded.

It comes, then, to this, that if we are to split coal out in large blocks, with small waste by dust and powdered coal and slacks, we must free it first either above or below. We can then split it out, no doubt, but *cui bono?* what will be the use of wedging from behind to split out masses of coal which, when once properly undermined, will rapidly fall by their own weight, and then detached from roof, floor, and "heading" or "wall," leave nothing to be done but to break them up smaller, and to sizes to be loaded on to the "corves," all which must be done, as at present, by hands in any case? This is the case with all moderately thick coal beds, even though they be perfectly flat and level. It is much more the case with highly inclined beds, like those of Belgium and Westphalia, which are worked on the long wall system from the under side, and along "the strike" of the beds, and from which the blocks of coal, once under or over cut, fall of their own accord, often but too readily and suddenly.

But at this time of day there is probably not an intelligent and well-informed coal viewer in Great Britain (and few of these gentlemen are not both one and the other) but is prepared to admit that under-cutting by coal-hewing machinery of one sort or other is already an accomplished fact, and that time, and not a long time, alone is needed for the wide-spread introduction, as a matter of necessity, of coal-cutting machinery in all our great collieries. Well, then, we have the coal cheaply, economically as regards the waste coal, rapidly, and deeply under-cut; we cannot get rid of the coal hewer, he must be there to direct and to fashion to a portable shape the huge blocks got out; he is on the spot, therefore, to hole or cross-cut the huge blocks as these drop from the roof, and by their own weight part off from the face of coal behind; of what use, then, are the hydraulic wedges, or hydraulic plungers at all? They appear, under such conditions where alone they can be applicable, as simple surplusage, for no sane man, we presume, will imagine the physical possibility of forcing out *thin-seam* coal while still gripped both by roof and seat.

Thus much for splitting in general, and without reference to the mode of attempting it. Granted the necessity and the utility of the plan of working, we are very far from being satisfied that any one of the actual arrangements proposed even approaches the best possible, or even a workable form at all, for the purpose. We shall not go into details, but merely ask our professional coal viewing readers to ponder, in a practical mood, upon the facilities, or the contrary, for working straight and cylindrical holes of four to six inches diameter into various sorts and thicknesses of coal, and under the various and often complicated conditions in which the workings are circumstanced.

We ask whether these hydraulic wedges or presses, said to be 50 lb. weight each, but actually much nearer probably, if ever brought into a workable form, to 150 lb. weight each, and which *must* be carried about and *manually* handled, will prove convenient? Whether in friable and compressible coal much more of the power expended will not be absorbed in crushing the coal close by to powder, than in splitting off that more remote? and whether, in any one of the arrangements, but most of all in Mr. Bidder's wedges, a prodigious proportion of the power expended be not necessarily always wasted? and if power be wasted in any machine, time is wasted, and money is wasted.

If a choice is to be made between hydraulic driven wedges and hydraulic driven plungers, between the power of the hydraulic cylinder, which may be at once brought up to any pressure we like per square inch, applied direct to the coal, or to that awkwardly exalted by the interposition of wedges—we are compelled to give our voice in favor of the simple and direct application of the hydraulic plunger. All wedges driven by pressure act at enormous mechanical disadvantage as wedges; work is uselessly absorbed in friction, and the loss so produced is greater as the angle of the wedge is less. The very essence, it may be said, of the wedge as an efficient mechanical engine depends upon its being driven, *not by pressure, but by blows.* At each blow the friction of rest, constantly encountered by the wedge driven by pressure, is by the sudden jar converted into the friction of motion, the coefficient of which for the same surfaces and pressures is usually not much more than one-half of the former.

With the hydraulic cylinder applied direct, the real limit to the intensity of the pressure per square inch of pressing surface is that of the crushing coefficient of the coal. That makes the limit really a low one, and hence we will hazard the conjecture that were these coal-splitting contrivances likely to be called into actual use and practice, it would probably be found that perhaps the very best form in which hydraulic pressure could be applied at all, might prove to be in that of a modification of Joseph Bramah's original leathern water-bag. We have, now-a-days, materials and methods at hand for the construction of flexible, or partially flexible bags, into which water could be forced to all the pressure the coal would safely bear without crushing, such as were unknown in his day, and the structural problem presents few difficulties to the mechanical engineer. Upon the whole, and in conclusion, however, we continue to believe that it is the perfectionizing of coal-cutting machinery, and not to coal-splitting instruments, even though far better designed than any that we have been noticing, that we ought to look for attaining the unquestionably most important ends of saving risk by limiting the use of explosives, cheapening our coal-getting, and economizing our coal itself.

THE SPECTROSCOPE IN THE BESSEMER PROCESS.

Compiled from "Oestr. Zeitschrift," and adopted by Dr. Adolph Schmidt.

A number of years ago, when the Bessemer process first began to regularly produce materials valuable for trade and practical use, the difficulty of operating the process in such a manner as to obtain by it a metal of certain qualities as desired, was at once recognized. Besides other means conceived to obviate this difficulty, the use of the spectroscope also was then proposed and tried. It was expected that the changes in the appearance of the Bessemer flame, which take place towards the end of the process, and which are evidently due to chemical changes in the constitution of the metal, could be observed more accurately with the help of the spectroscope, and would thus make it possible to interrupt the process at the precise moment when the required degree of decarburization of the metal is obtained. It appears, however, that the results of these experiments were not satisfactory, from the facts that no detailed account of them has been published, and that the use of the spectroscope was not continued afterwards. About two years ago Professor Lielegg, of Gratz (Styria), took up this matter once more. By a series of experiments made by him at the Gratz Bessemer Steel Works, and published in 1867 in the reports of the Austrian Imperial Academy of Science (see "Dingler's Polyt. Journal," vol. 16, 1867, or "Berg. u. hm. Ztg.," 1867, No. 12 and No. 48), he discovered that under the most different circumstances, and with the most different pig irons, the Bessemer flame, when analyzed with the spectroscope shows, besides some varying and accidental lines produced by accessory constituents of the pig iron, a constant spectrum, consisting principally of several groups of black, green and blue lines. These lines are not to be seen at the very beginning of the process, they become visible in the second period only, when the temperature is more elevated and when the carbon begins to burn in a more lively manner. They remain visible and bright until, in the third period, they disappear one by one, simultaneously with the diminution of temperature caused by the lack of carbon in the metal. Professor Lielegg attributed this spectrum to the carbonic oxide gas, and designated the single lines, accordingly as C Oα, C O β, C Oγ, etc. He also found that the observation of the gradual disappearance of these lines has a practical value, because not only the moment of nearly complete decarburization (what is called "the change" by practical Bessemer men) can be determined more accurately, but also because different kinds of products may be obtained by making the interruption of the process dependent on the disappearance of the one or the other of the said lines of the spectrum. Thus the spectroscope came into regular use at the Gratz Bessemer Works. The results obtained at Neuberg (Styria) were, however, widely different from the above. The Neuberg works convert almost exclusively their own pig iron, which contains a considerable amount of manganese (three and a half per cent). This iron, in being converted by the Bessemer process, develops towards the end of the charge an opaque flame full of white smoke. This smoke is the thicker and the less transparent, the hotter and better the charge. By inserting a wrought iron pipe terminating in a receiver into the mouth of the converter towards the end of a charge, Professor Kupelwieser succeeded in obtaining a certain quantity of the solid matter which constituted this smoke. Mr. Schöffel, who analyzed it, found it composed of—

$Si\,O_3$ (Silicic acid)	34.86
Mn O (Protoxide of manganese)..	48.23
Fe O (Protoxide of iron)	16.29
	99.38

This smoke, which seems to be principally due to the presence of a considerable quantity of manganese volatilized at a very high temperature, as silicate or as protoxide, covers the Bessemer flame in hot and good charges to such a degree that the observation of the "change" becomes often extremely difficult, and it is proved by numerous experiments that, in this case, the spectroscope is of no use whatever, because the Bessemer spectrum then disappears completely. It has, besides, been noticed, that even in less hot and less smoky charges the spectrum is only visible intermittently, and often disappears before the iron is near the point of complete decarburization. In such a case spectroscopic observation is not only useless, but can lead into errors and mistakes.

However the spectroscope is still in regular use at Gratz, and Ternitz, in Austria, at Maximilianshütte, in Bavaria, at Marienhütte, in Saxony, and some other German Bessemer works which do not convert manganesic pig irons. But few, if any, of these works make their operations exclusively dependent on the spectral indications. It has been mentioned above that Professor Lielegg considers the Bessemer spectrum as identical with the spectrum of carbonic oxide. Professor Kupelweiser has expressed the same opinion. But Mr. Brunner, an Austrian metallurgist, has shown in No. 29 of the "Oestr. Zeitschr.," 1868, that this view is incorrect. According to Lielegg's own investigations, carbonic oxide gas when burnt with oxygen produces, under all circumstances, a continuous spectrum without any light or dark lines. Lielegg attempts to explain the different appearance of the Bessemer spectrum by the higher temperature. It is, however, not probable that the temperature of the Bessemer flame should be higher than that of a flame of carbonic oxide mixed with oxygen in Daniells' cock. Besides some of the characteristic lines of the Bessemer spectrum have been observed in the flame which is produced by the heating of the converter previous to the charge, when evidently a temperature as high as the one mentioned does not exist. Brunner has also discovered, that no part of the Bessemer spectrum is ever visible in the flame when the converter is heated for the first time after being relined, but that when the lining is not new the group of lines called C Oγ by Lielegg appear in the green part of the spectrum, which then contains also the lines of potassium, sodium and lithium. Mr. Brunner concludes, from these facts, that this spectrum is not to be identified with that of carbonic oxide, but must be produced by other constituents of the pig iron. In further considering that it would be very strange if iron and manganese would not produce a spectrum at so high a temperature, he thinks it probable that the Bessemer spectrum is principally produced by these elements. In fact several of Lielegg's pretended C O lines coincide with the black iron lines as defined by Prof. Kirchoff, of Heidelberg, who is one of the inventors of the spectrum analysis. Also Lielegg's line C Oη, which is violet blue, and situated so near the potassium line K β that both lines almost appear like one broad band, corresponds to the violet blue line, Mn_5, in the spectrum of manganese. Brunner besides suggests that Lielegg's group of lines, C O B and C Oj, might be identical with the yellowish and green manganese lines, Mn_1, Mn_2, Mn_3 and Mn_4.

This suggestion has been fully verified by more recent investigations made at Neuberg, in December, 1868. As these investigations have been made in a peculiar manner, specially adapted to compare two different spectra with the greatest accuracy, thus to ascertain some supposed total or partial identity, we here reproduce a short description of them, as published by Mr. A. v. Lichtenfels, in "Oestr. Zeitschr.," 1869, No. 2. The instrument used for the purpose is a pocket spectroscope of the manufacture of M. Hoffman in Paris. It consists of a tube six inches long and three-quarters of an inch in diameter, containing two prisms of flint glass, three prisms of crown glass and one lens. The latter is placed near one end of the tube, opposite the slit through which the rays of light enter. Its object is to make the rays parallel. A small telescope with four lenses is attached to the other end of this tube by means of a joint, by a slight motion of which any desired simple ray can be directed to the center of the field of view. A small glass prism, about five-sixteenths of an inch long, can at option be attached to the outside of the instrument, in front of the slit, covering only one-half of the latter, so as to allow of the simultaneous observation of two sources of light.

The light of the Bessemer flame passes through this glass prism by reflection into a part of the slit, through the other part of which enter the rays of another well known source of light, prepared for comparison. Thus the spectra of both sources of light appear side by side in the field of view of the telescope, and if an elementary body is equally present in both flames, the characteristic lines of that body must correspond exactly in both spectra, because the rays from both lights enter through the same slit and are refracted by the same prisms. This is the most reliable method of analysis by the spectroscope. The bodies destined for comparison are dissolved in alcohol, and the solution is poured with a spoon on a small dish of platinum, heated to a white heat, where it rapidly evaporates. It is very important to produce a flame as hot and bright as possible; for it would be difficult to see a weak spectrum at the side of another one as bright as that of the Bessemer flame.

To make a comparative experiment with the described instrument, at first the exterior glass prism has to be fixed to its place; after this the whole apparatus is set in such a position that the spectrum of the Bessemer flame can be seen through the tube; afterwards the platinum dish is placed in front of the object-glass and heated by a lamp, and finally the testing fluid is poured on the dish. Burning alcohol produces no other but the sodium line. The spectra of calcium (here chloride of calcium) and of copper (here nitrate of copper) were compared, but did not coincide with the Bessemer spectrum. But the spectrum of manganese (here chloride of manganese) corresponded perfectly. This spectrum, according to Simmler, consists of four broad green bands and one violet blue line situated quite near the potassium line of the same color. These green bands appear in the Bessemer spectrum as groups of green lines in an exactly corresponding position. Two of these groups of lines are very distinct; the two others which are situated nearer the blue field, are less bright. The optic power of the instrument was not sufficient to show the violet blue line distinctly in either of the two compared spectra. However the main part of the question is solved by these experiments, and it is proved that the Bessemer spectrum, in its principal and characteristic features, is not the spectrum of carbonic oxide, but that of manganese. As "the change" in the Bessemer process (that is the exterior signs which indicate the almost complete removal of the carbon from the metal) could only be made dependent on a spectrum produced by carbon or its compounds, the use of the spectroscope in this process has, in fact, no general and scientific foundation, but is based, wherever it is used with success, on the happy coincidence that the greater part of the manganese is removed from certain kinds of pig iron, when subjected to the pneumatic process, at about the same time as the main part of the carbon.

THE COMPOSITION OF CEMENTS.

From "The Building News."

The value of all cements must of necessity depend upon their composition. There are two distinct kinds of cement, with three distinct names—the calcareous, the hydraulic, and the plastic. The calcareous is everywhere known by the name of mortar, or that mixture of lime and sand commonly used for building. The hydraulic cements are those which will set under water, and the plastic cements are such as are applicable to plastering and stuccoing. Of lime there are many varieties, each of different merits. Vicat classified them as—1, rich limes; 2, poor limes; 3, limes slightly hydraulic; 4, hydraulic limes; 5, highly hydraulic limes. As there are different qualities of limes, so, of course, there must be of limestones. It has long been held, and universally proved, that the harder the ingredient the better the quality of the lime; that the best materials are those that dissolve the quickest, heat the most in slaking, and fall into the finest powder. It should be remembered, however, that each variety yields a lime of different quality—different in color, in its power of absorbing water, and varying in weight and in hardness. The rich limes are the purest oxides of calcium; they increase to double their bulk in the process of slaking, which is not the case with poor limes. Limestones containing from one to six per cent of foreign substances, such as silica, alumina, magnesia iron, etc., yield rich limes. The limestones may differ in appearance and in texture, yet if well calcined the lime will be the same. Soft chalk, hard ragstone, or marble, yield equally good lime, since the calcium they contain is the same mineral. Chalk, however, generally contains water irregularly distributed, and, not exhibiting the same change that marble or stone does, it is frequently unequally burned, and therefore slakes imperfectly. Dr. Higgins states that lime made from chalk absorbs the carbonic acid more rapidly than that made from stone, but the experience of others (the late Mr. Arthur Ashpitel notably) has not favored this conclusion. The mode of burning varies, but the general result is the same.

The resulting quicklime is lighter than the original stone, and differs essentially from it.

Poor limes are obtained from limestones which contain silica, magnesia, manganese, or metallic oxides. These foreign substances are present to the extent of from 15 to 30 per cent. They do not slake freely, and they are more liable to vitrify in burning. Oysters or cockle shells are found to vitrify more easily than limestone or chalk when suddenly heated, which is attributed to their saline matter, for when they have been long exposed to the weather they do not so easily vitrify. In proportion as limestone contains gypseous or argillaceous particles does it vitrify. Limestones containing much silica swell in setting, and may dislocate the masonry executed with them. If alumina be in excess the lime is apt to shrink and crack. If carbonate of magnesia be combined with carbonate of lime, as is the case in magnesian limestones, the original bulk is retained.

The mixture of hard, sharp particles—the harder and sharper the better—is necessary for various reasons. It facilitates the setting of the mortar, it renders it much harder and much more adhesive, and saves expense. Three kinds of sand are used in building purposes, but only two are employed for cements. River sand and pit sand only should be admitted into the composition of mortar, and the former is preferable, as it is free from clay. Pit sand should be well washed. Crushed quartz or flint, from its sharpness, has been considered to be the best material. Many builders use road-drifts, and have found it to be a fair substitute for sand, and withal economical. The Romans used burnt clay, in the form of pounded brick, very extensively; and the present method is to throw up clay mixed in any fuel in loose heaps and burn it slowly. Burnt clay was, indeed, largely used and advocated in France. Used as hydraulic mortars in large public works, it was found that the action of sea-water soon made them crumble to powder; and it was only in fresh water that the mortar stood well. Slag from furnaces and the scoriæ from the iron-works have also been used for sand; the latter not so frequently, on account of the iron found in it. Coal cinders have been used, but not with much success, and wood cinders, which, however, are found to be too alkaline for the purpose. These materials have a considerable effect in hastening the absorption of the moisture and facilitating the setting of the limes with which they are used. Puzzuolana—so called because originally found in the vicinity of Puzzuoli, near Naples—is a volcanic material. The following analyses of this material were given by Professor Ansted in his Cantor Lectures at the Society of Arts in 1865. We observe that they vary a trifle from the analyses given by the French writers:

	Puzzuolano.	Trass.
Silica	44.5	57.0
Alumina	15.0	12.0
Lime	8.0	2.6
Magnesia	4.7	1.0
Iron oxide	12.0	5.0
Potash	1.4	7.0
Soda	4.0	1.0
Water	9.2	9.6

The French writers consider that the mixture of common lime with these materials should be one of pounded lime to two and a half of puzzuolano, or to two of trass (or terrass), or one of lime to one of sand and one of puzzuolano. The matter, however, is largely one of economical calculation.

A good test of the purity of sand, and a most important one, is the homely practice of rubbing it between the hands If it be fit for use as mortar it will not soil the hands, and will be free from odor. Dr. Higgins, whose experiments on sands have made him an authority on the subject, has pointed out that mortar made with sand whose grains were about equal in size and globular, could not be so strong at any period of induration as that which is "mixed with as much fine sand as can easily be received into its interstices, in order that the lime may cement the grains by the greater number and extent of their contiguous surfaces." He also states that the sand that passes through a sieve *in washing* is finer than that which may be sifted through the same sieve when dry. Sand is never non-absorbent and imperishable, and therefore it is needful it should be pure when used for building purposes. The mediæval builders knew this, and hence the fine characters of their masonry.

The results of experiments made by Dr. Higgins, and detailed at some length in his work—now, we believe, out of print—are of considerable importance. Very briefly summarised, they may be thus stated: The interstitial spaces in sand are greatly lessened by wetting it; therefore he determined in using it for mortar to wet the sand completely. It was thus, too, that the air was easily expelled, and the lime equally diffused itself in the spaces by a little heating; but when, as he says, the water is added to a mixture of lime, powder, and sand, the air is entangled in the lime paste, and cannot, without a great deal of heating, be totally pressed out of the plastic mass. As an excess of water is injurious to mortar, this was found to be an excellent way to regulate the quantity used, "for the portion of lime water which fills the spaces in sand, and can be held by capillary attraction in a flat heap of it, is precisely the quantity which makes well-tempered mortar with one part of the best slaked lime and seven of the best sand." Other investigations showed that there were two kinds of grains, which Dr. Higgins denominated "sharp" sand and "round" sand. The conclusion of all his experiments goes to show that the quantity of lime which forms a mass somewhat plastic with sand and water, is the smallest quantity necessary for making the best mortar from such sand. Any further quantity of lime would be useless in the coarser sands and injurious in the finer. The necessary plasticity is induced by the smaller quantities of lime. The grains of fine sand are, he says, held asunder by the lime paste to a greater distance than they are by water, and "the reason why the finer sand requires more lime than the coarser and mixed sand is, that the spaces, which are more numerous in fine sand than in the coarse, are more augmented in the whole quantity of them by the particles of lime which intercede alike the coarse and fine grains."

We have already said that river sand, or "silt," is the best of all the kinds of sands used for building purposes. Pit sand is too fine, and not so sharp and gritty. Coarse and fine sands, then, should be mixed in order to obtain a good cement, since the finer grains fill the interstices of the larger, and so tend to consolidate the whole mass. The two ingredients should not be mixed before slaking, but the bulk of the water should be applied to the sand before it is mixed with the lime, Dr. Higgins' experiments teaching us that in this way the air is more easily expelled from the mass, and the mortar, therefore, is of a more endurable nature. This being so, the common practice of "duffing builders" in running up new houses to use sands without first washing them, indeed to use any kind of rubbish—sand mixed with organic matter—is discreditable. Surely, when the materials "found on the spot" are used, it is only common honesty to regard their quality, and to remove from them the deleterious matter with which they are charged.

It is important that all water used in making cements should, at least, be fresh. In any case it should not be polluted, stagnant water. All vegetable and organic matter should be as much excluded from the water as from the sand into which it is thrown. Ordinary water contains some acidulous gas, and therefore it has been recommended that no water should be used until the gas had been freed from it. After making several experiments, it was found by Dr. Higgins that lime water is far preferable to any other. On comparing specimens of mortar made with the best lime slaked with river water, and sand and water, and spread on tiles soaked in water, with other specimens made with the same proportions of lime, but *slaked with lime water*, and sand and lime water, and spread on tiles previously soaked in lime water, the latter at every stage of them were sensibly harder, and they adhered to the tiles better than the former. He adds that he had good reason to be persuaded that the extraordinary induration would proceed in time through the whole mass. Of course, it is not difficult to adopt this plan, since lime water is readily made by dissolving lime in large casks or tanks.

We have thus considered the main principles which affect the three ingredients of mortar—the lime, which is the cementitious medium, the sand, which is the matter to be combined, and the water, which is the combining element or agent. We have now to look—space compelling us to do it with the utmost brevity—at what preachers would call a few matters of application. The mortar must be durable; free, by its very compactness, from damps and atmospheric influences, and thus those much dreaded enemies, expansion and contraction, avoided.

These results are alone attainable by attending to the judicious combination of the various ingredients. Given pure materials, the best combination is proved to be one part of lime to five, six, or seven parts of sand, the latter varying, of course, with its nature. Pit sand requires more lime than sharp river sand or clear road drift. Coarse sand requires less lime than fine sand. Mortars made with common fresh lime, or with well burnt lime, but containing only one ounce (say) of lime in six or more of sand, have been found by some experimenters to be the best. An excess of lime may dispose the mortar to crack. According to Dr. Higgins, the highest proportion of lime to coarse Thames sand which may be used with safety depends on the circumstances in which the mortar is to be exposed. "No more than one part of lime to seven of coarse sand ought to be used in mortar which is to dry quickly, and less lime may not be used because it does not render the mass sufficiently plastic for building and incrustation." At the same time, if a larger proportion of lime be used, it should be only when the mortar cannot dry so quickly as when exposed to the sun. But hasty drying, it has been proved, frequently injures mortar. Then, again, if the lime be carelessly or imperfectly manufactured, the mortar cannot be other than imperfect. The lime should be screened about half an hour after the workmen have thrown the water upon it. When they slake lime mixed with sand or gravel in great heaps, without screening it—which is more frequently done than not—the mortar is not likely to be very good.

Lime very quickly imbibes the acidulous gas which has been expelled after burning if it be exposed to the air. Indeed, it cannot long preserve its virtues without confinement in air-tight vessels. Experiments have demonstrated that lime undergoes changes quickly; indeed, well burned chalk lime, kept in a dry room, will imbibe about a pound of acidulous gas in three weeks in the summer months, so that the longer it is kept, the worse it becomes. Workmen are apt to think it is sufficient to keep the lime dry, and store it in ricketty barrels. This is not the case. Lime may be greatly impoverished witout slaking sensibly. "The superficial parts of any parcel of lime. which fall into fragments or powder without being wetted, and merely by exposure to air, are quite unfit for mortar, since this does not happen until they have imbibed a great deal of acidulous gas." To prevent common cements being bad or imperfect, the lime should not be exposed a great while before it is converted into mortar. If this be not done, the lime will be reduced into a perishable kind of whiting; indeed, bad lime, bad mortar. Imperfectly burned and unprotected lime will only give a builder a poor article, and we are writing, of course, for those who do esteem a good common cement; and the quicker it is used, and the less exposed to the deteriorating influences of the atmosphere, the better material will it be.

ENGINEERING CHEMISTRY.

From "Engineering."

Chemistry, though the grandest of the sciences, and scarcely older than the present century, is probably second to none in the importance of its bearing on most branches of industry. But, notwithstanding this fact, the cultivation of chemistry as a science is, in this country, left entirely to the accidental interest of individuals; and it is almost exclusively in connection with medicine that the principles of chemistry are taught at any of our educational establishments. We have not, in this country, a single chair of general applied chemistry, and, with the exception of the professorship of metallurgy at the Royal School of Mines, there is no provision for teaching the special application of chemistry to any branch of industry. Though we have some able chemists, their functions are almost entirely educational, or they cultivate chemistry merely as amateurs, while the application of chemical knowledge and skill to industrial art is so far from being recognized as a profession, that, like engineering a century ago, it is a pursuit offering little definite prospect to those who might be disposed to follow it, and one that is taken up only under chance circumstances. We are, however, of opinion that there is not only room for, but a great need of, a class of competent chemists who would devote themselves to the practical applications of this science, and to whom manufacturers, engineers, and others, could safely apply for advice and assistance in cases involving the consideration of chemical principles and knowledge. Among engineers generally it is, in this country, very seldom that any great acquaintance with chemistry is to be met with; and even manufacturers, as a class, do not generally possess such an amount of chemical knowledge as would be desirable and necessary for the most efficient practice of their arts. Nor can it be expected that either engineers or manufacturers should in any case become so far masters of chemistry as to supercede the necessity for advice and assistance from those who have specially devoted themselves to the study of the science in its practical bearings. One of the most serious obstacles that stand in the way of the formation of any such class of professional chemists as we have referred to, is the absence of any criterion by which the competence of chemists may be judged of, and qualified men distinguished from the host of quacks and charlatans who dub themselves chemists. Consequently, the only thing by which the public can be guided, is the fact of a chemist holding some position or office, of which there are, in this country, hardly any which are not purely educational. Even those are very few compared with the want that exists for sound chemical teaching, and those few chiefly fall to the lot of chemists who devote their attention to abstract chemistry rather than to its practical application. We do not pretend to say how any wider criterion of chemical competence is to be established, but we do not hesitate to express the opinion that it is very much needed at the present time.

As regards more especially the application of chemical knowledge to engineering, there are unquestionably many branches of this profession in which it would be of the greatest value, and somewhere it is indispensable. Thus, for instance, in regard to the subject which is probably the greatest engineering problem of the time, viz , the disposal and utilization of town refuse, and the waste products of manufactories, etc., together with the maintenance of rivers and other accumulations of water in a proper condition, both as means of communication and sources of water supply for towns; it is impossible that it should be properly dealt with unless the chemical aspect of the subject is fully considered. Indeed the many serious evils arising from polluted rivers, sewage infection, and the waste material that would be of service in maintaining the fertility of land, are in a great measure to be ascribed to the one-sided views under which the present system of disposing of town refuse by water carriage was introduced, and to the disregard of those chemical principles which would have indicated the probable consequences of that system unless it were supplemented by measures for dealing thoroughly with the material to be removed, and not merely transforming its noxious influence from one locality to another. To this circumstance also must be ascribed the dead lock now existing in regard to sanitary regulations, and the improvement of the condition of towns by the construction of sewers.

The subject of artificial illumination and the questions as to the requisite purity and proper cost of illuminating gas constitute another field in which the services of the practical chemist may be of advantage to the engineer, and where the co-operation of engineers and chemists can alone be expected to lead to satisfactory results. Not in any way less important, or less capable of improvement by such united efforts of engineering and chemical skill, is the subject of economy of fuel. In the production of motive power, in the heating of dwellings, the various branches of metallurgic art, and in many other cases where fuel is employed, the quantity consumed is vastly in excess of that requisite for effecting the objects in view. Improvements in this direction would be a source not only of individual profit, but also of national advantage. We might extend the illustration of our views on this subject almost indefinitely, but we apprehend the possible profit of and urgent need for greater attention being paid by engineers to chemistry is very widely appreciated in the profession, and therefore we confine ourselves to mentioning the subject, in the hope that others may suggest a means of giving practical effect to our views, and make some effort towards carrying them out. The recognition of science by the State is as yet a principle too little acted upon in this country to warrant much hope of this idea being promoted from that direction; but our private societies, such as the Institution of Civil Engineers and the Society of Engineers, are sufficiently strong to take the initiative in this matter, and they might do good service by giving their support to some feasible plan for bringing chemistry more within the range of the engineer's notice, and making chemical knowledge more readily attainable by him than it is now.*

DEVELOPMENT OF CHINA.—The formation of a society is being actively promoted in Belgium with a view to the introduction of railroads and telegraphs in China, and the development of its mineral wealth. The project is favorably viewed by King Leopold, who has traveled in China.

---

* These are timely considerations for America as well as for England, although the amount of sound chemical knowledge and practice in the arts would appear to approximate to the demand more nearly here than abroad. Our excellent schools are gradually supplying the want mentioned above, but they should be better endowed. The best thing governments and rich men can do is to give money to scientific schools.—ED. *Van Nostrand's Magazine.*

THE BESSEMER PROCESS IN THE MANUFACTURE OF COPPER.

By Franz Kupelwieser, Professor at Leoben, (Austria).

Translated from Oester. Zeitschrift.

No metallurgical process using exclusively atmospheric air as oxidizing agent, is able to produce a quicker and more energetic oxidation than the pneumatic or Bessemer process. It, therefore, must appear strange that this process has not yet been used in any other metallurgical manufacture than in that of iron and steel, although oxidation plays such an important part in the manufacture of other metals, that their separation from each other and their purification from noxious ingredients can in many instances not be effected without it. The reason why the pneumatic process has not before been used in the manufacture of other metals may be the following: The expenses for machinery necessary to make such experiments are considered to be very high. It is feared that a great loss of metal will result from the pneumatic treatment of most of these metals. It is expected that experiments of this kind would have to be made on a large scale, and consequently with a risk of considerable quantities of metal, because it has been experienced in the treatment of iron, that the Bessemer process does not work to advantage when applied to small quantities.

In considering, however, that the melting-points of most of the other metals and of their sulphides, when subjected to oxidizing processes, do not rise to such an extent as that of pig iron does in being converted into steel or soft iron, but that the products of such processes generally melt as easily as the original substances or compounds, it appears more than probable that the heat produced by the combustion of the matters to be oxidized, will be sufficient not only to replace the heat lost by radiation, but also to keep the final products in a fluid state even then, when the process has been carried on with smaller quantities. For small quantities of metal, small vessels only and less powerful blowing apparatus are required, and the absolute losses of metal caused by unsuccessful experiments, are less to be feared.

To further encourage proprietors of metallurgical works to undertake such experiments, I publish the result of a successful trial of this kind, as communicated to me by the Russian mining engineer, Mr. Jossa.

This trial was made in 1868, at the smelting works of Wotkinsk, in the Ural Mountains (Russia), with coarse metal of the following composition:

Copper	31.54
Iron	39.41
Sulphur	25.29
Calcium	1.26
Slag	0.95
	98.45

Charges of 40 pud=1,450 lb. avoirdupois of this metal were made in a small English Bessemer converter. This converter had been constructed originally for trials with pig iron, and had a capacity of 100 to 120 pud of iron. It was, therefore, too large for the mentioned quantity of copper metal. An abundant quantity and pressure of blast was furnished by the existing blowing engine, and the conversion was lively and rapid. It was intended in these first trials only to concentrate the metal, and not to produce black copper. To see how long the blowing was to be continued to advantage, samples of the slag were taken at different stages of the process. They were analyzed afterwards and were found to be composed of:

	No. 1.	No. 2.	No. 3.
Silicic acid	34.46	29.46	27.20
Alumina	4.73	3.13	2.26
Lime	3.06	2.53	2.00
Magnesia	0.33	0.28	0.28
Sesquioxide of iron	55.26	57.24	58.55
Peroxide of copper	2.13	8.46	8.53
Sulphur	0.11	1.68	1.77
	100.08	102.78	100.59
Containing metallic copper	1.70	6.75	6.81

The product of the operations was concentrated metal, composed as follows:

Copper	78.90
Iron	0.94
Sulphur	16.63
Calcium	1.04
Slag	2.44
	99.95

From these notes, as communicated to me, the following inferences may be made. The coarse metal used is to be considered as one of the purest ever made, not containing any antimony, nor arsenic, lead, nickel, &c. The only object of the oxidizing operation was, therefore, the scorification of the iron, so as to obtain a concentrated metal with a higher percentage of copper. The last of the above analyses shows that this task has been fulfilled by the pneumatic process in a very complete and satisfactory manner. The iron in the metal has, in fact, been diminished to such an extent that the product, after being calcined, can be converted into a very pure black copper by a single melting process. It appears that when air is blown through melted copper metal, the oxygen does not affect the copper as long as a sufficient quantity of iron and sulphur is present. The iron is burnt to protoxide, which unites with the slag, and a considerable part of the sulphur is burnt to sulphurous acid, which escapes. I may add some remarks on the analysis No. 3 given above, which shows the composition of the slag obtained, together with the concentrated metal, at the end of the process. This slag is very nearly composed like a singulosilicate, and melts pretty easy, the greater part of its basic constituents being compounds of metals. According to Plattner's rules of estimation, its melting point would be about 2300 deg. Fahr. It is remarkable that the copper occurs in these slags as peroxide, as it is generally found to be present as protoxide in such kinds of slags.

As the slag No. 3 contains 1.77 per cent of sulphur which would combine with 6.34 per cent of copper, forming a protosulphuret, it seems probable that the greater part of the copper found in the slag, exists there in this combination, as small particles of metal, being mechanically mixed with the slag. Thus the copper really oxidized and scorified would be reduced to a very small percentage.

By means of the above analyses and of the given weight of the coarse metal subjected to the process, the weights of the products may be approximately calculated thus:

Weights in Pounds.

	Coarse metal.	Concentrated metal.	Slag.
Copper.........	413.2	342.0	71.2
Iron...........	516.2	4.2	512.0
Sulphur........	331.3	72.1	19.9
Calcium........	17.5	4.4	
Slag...........	32.2	10.6	
Oxygen, silica, &c.	....	....	525.6
	1,310.4	433.3	1,128.7

It is seen, from this calculation, that the amount of slag is very large when compared with the quantity of concentrated metal produced. As this slag contains a considerable amount of iron, its specific weight cannot be very much lower than that of the metal, and the separation of the latter will take place slowly. The products have, therefore, to be kept in a fluid state for some time at the close of the process, so as to avoid unnecessary losses of metal. Should the slag, however, contain a noticeable percentage of copper, it can be melted over again in the blast-furnace, as is generally done with the slags resulting from the ordinary concentrating process. A large amount of protoxide of iron being formed during a pneumatic charge made with coarse metal, a considerable quantity (306 lb.) of silica is required to scorify it. It might, therefore, prove advantageous to add a certain weight of silica to the charge to prevent a too rapid destruction of the converter-lining. As regards the quantity of blast required for the process, no direct data have been given to me. But this can easily be calculated from the amount of oxygen necessary for the oxidation of the different substances that were removed by the process from the original coarse metal. In neglecting the small quantities of calcium and copper oxidized,

512 lb. of iron were oxidized with	146.2 lb. oxygen.	
240 lb. of sulphur do	240.0 "	
Total oxygen............	386.0 lb., or	
	4,246 cub. ft. (Austrian),	
To which added	15,973 "	of nitrogen,
Gives us........	20,219 "	of air.

Consequently about 1,500 cub. ft. of atmospheric air are required for every 100 lb. of coarse metal treated. From this the duration of a charge may be estimated at nearly 20 minutes.

The advantage resulting from the use of the pneumatic process in the manufacture of copper is chiefly this, that it enables us to convert the coarse metal directly into a metal so perfectly concentrated that, after being calcined, a single smelting operation will work it into black copper. Thus one calcining and one smelting operation are entirely avoided and the corresponding time, fuel and labor are saved. Continued experiments will decide in regard to the point up to which the process has to be continued, to obtain slags as poor in copper as possible. This process is, however, advantageous only in the larger copper works, where the ores are melted in large reverberatory furnaces holding as much metal as is required for a Bessemer charge, so that the coarse metal produced in these furnaces can be run directly into the converter without being remelted.

It is, nevertheless, desirable that further trials be made to make useful, for the manufacture of copper or other metals, a process which achieves so great things in the metallurgy of steel and iron. S.

FIRE AND BILGE PUMPS IN SHIPS.

ON THE LOCATION OF INDEPENDENT STEAM FIRE AND BILGE PUMPS IN STEAMERS.

From a paper by CHAS. H. HASWELL, Civil and Marine Engineer, New York, read before the Institution of Naval Architects.

Of all the instruments and appendages connected with a marine steam engine, and the provident fitting of a steamer, the independent steam pump, or donkey, stands preeminent in importance; both on account of its general utility and its being, under many very probable and oft-occurring circumstances, indispensable to the safety of a vessel. The applications of this instrument extend from the ordinary operations of a bilge pump and a boiler feed pump, to those of a fire and a hold discharge pump.

When, therefore, the extended, and in many cases, the indispensable operations of this instrument are duly considered, it would seem to be imperative that it should be located where it can be most readily reached, and where it can be operated for the longest period without being submerged by water, enveloped in smoke, or cut off by fire.

It occurs, however, that as a rule of British and European practice, that it is located in the hold of steamers, immediately upon the lower engine room floor; this practice taken in connection with the insufficient capacity of the pump for the general purposes of fire and leaks, would seem to have arisen from the functions of the pump, as viewed by the constructors of the engines, being restricted solely to the operation of feeding and pumping out boilers. The cases in which the location of the pump in the manner referred to are objectionable, are as follows:

1. A leak occurring in the furnace or water bottom of a boiler, and the hot vapor arising therefrom precluding access to the pump, and the setting of it in operation, whereby the water escaping from the boiler, not being replaced by the operation of this pump, would soon expose the tubes or crown plates of the furnace to be burned, and the boiler rendered thereby unsafe for operation.

2. A leak in the hull of a steamer suddenly occurring from a collision with ice, another vessel, a pier or a sunken rock, or the disruption of the propeller shaft stuffing-box in a propeller, whereby the influx of water would be fully equal to the combined capacities of the pump and engines to discharge. The distance between the pump and the floor of the vessel, or the level of the water in the hold, would be so little, that any arrest of the pump from continuous operation, for adjustment or repair, would involve its submersion before it could be set in renewed operation.

3. A fire occurring upon the main deck of a steamer, whereby the smoke would be drawn into the engine and fire rooms by the draught of the furnaces of the boilers, and this pump rendered inutile by the impracticability of reaching it to set it in operation.

4. A vessel grounded or stranded upon a sand or soft bottom, and leaking; her pump, from the ingress of sand and mud into her hold, would require frequent clearance; the delays consequent upon which would cause the pump to be submerged before it could be freed and set in operation. The only defence that ever has been advanced for this violation of regard to the safety of a vessel, in locating this pump, where in many cases as here shown, it would necessarily be inoperative, is, that, in the event of the hold being flooded with water, the fires in the furnaces of a boiler would consequently be drowned, and that, the steam wherewith to operate this pump being obtained from the boilers, its functions would cease with the drowning of the fires. Admitting this position to be strictly tenable, it does not meet the conditions of this pump, being arrested in its operations by sand, mud, smoke or the escape of steam. The position advanced, however, is not one of general application, as in a majority of cases, and especially in this country, there is an independent boiler connected with this pump, which, when located upon the main or spar deck, and acting independently of the engine boiler, its functions would not be affected by the influx of water into the hold of a vessel.

The common plea, that a pump located in the hold of a steamer, below the water-line, will operate more effectively than if located upon the main deck, is only advanced by some engine drivers, whose conceptions of a steamer are restricted to the operations of the engines and their dependencies, or by some owners of steamers, who are disinclined to incur the cost of a removal of the pump to a proper location.

In this connection the capacity of this

pump, proportionate to the dimensions of the vessel, is worthy of consideration; and, as a further rule of practice, the capacity of this pump in British and European steamers is much inferior to that in use in this country. The general security of lines in British vessels, under the stringent requirements of Lloyd's rules, has not generally opened the subject of the propriety of using a steam pump for other purposes than those referred to, as confined to the operation of the boilers of a vessel; for, in many cases, this pump cannot be used to draw water from the bilge or hold of a vessel, and has not any fire hose connections beyond the immediate precincts of the engine room.

The capacity of this pump, proportionate to the vessel in this country, may be judged of from the following cases: A British steamer, now in this port, built upon the Clyde as late as 1867, and belonging to a leading company in the extent and character of its trade, presents the following cases: $l - \frac{3\,b}{5} \times b\,\frac{b}{2} = 3{,}230$ tons has but one independent pump, having a water cylinder of one gallon capacity, or a discharging capacity of 12,000 gallons per hour, or 3.7 gallons per ton per hour.

The new steamers of the Pacific Mail Steamship Company, built in this city in 1867, present the following cases:

$$\frac{l - 3\frac{b}{5} \times b\,\frac{b}{2}}{95} = 4{,}200 \text{ tons}$$

have four independent pumps, having water cylinders of $17\frac{1}{2}$ gallons capacity, or a discharging capacity of 136,500 gallons per hour, or 32.5 gallons per ton per hour.

In further support of the position assumed, I submit that there has occurred very many cases where steamers have foundered, burned or been wrecked in consequence of the location of their independent steam pumps in their holds. Three cases, and important ones so far as the loss of lives and property are concerned, can but be familiar to all. The Arctic, foundered at sea, 1854, had two independent pumps of a combined discharging capacity of 31,000 gallons per hour, and an attached boiler, all of which were located in her hold. When her bottom was perforated by collision with the sharp prow of an iron steamer, the influx of water was superior to the capacity to discharge it, and for the following causes:

1st. Her independent boiler could not be put in operation until steam was raised in it.

2d. Her floor being filled in solid, her bilge injections could not operate effectually until the water was fully two feet in depth, in consequence of the roll of the vessel.

3d. At the time sufficient water had flowed into the hold for the bilge injections to operate with their full capacity, the additional depression of the vessel occasioned by this influx of water had reduced the number of revolutions of the engines, and consequently their capacity to discharge the inflowing water, added to which, the water at that height washed the water bottoms and ash pits of the boilers, and reduced their capacity to furnish steam to operate the engines. Thus with a constant flow of water the capacity to discharge it was being rapidly lost,

It occurred, however, that there elapsed a period of four hours after the collision, before this vessel sunk, and as a computation made by me of her entire weight as a mass, less the actual displacement of every particle of her and her cargo, gave but a difference of 1,000 (one thousand) tons, it appears that the discharge of this weight of water, or 65,570 gallons per hour, would have left this vessel free of water, and enabled her, so far as that collision was concerned, to have reached a port of safety. Now, as the capacity of her bilge injections, at even the reduced number of revolutions of ten, would have been equal to 80,000 gallons of water per hour, it is manifest that the loss of this vessel at this time is directly attributable to the location of her independent pumps and their attached boiler.

The Austria, burned at sea in 1858, in consequence of the smoke from a fire upon the main deck pervading the engine room and suffocating the watch, and as a consequence precluding the operation of her pump as a fire engine. The Britannia, lately foundered at sea by the flow of water in her engine room, and the submerging of her independent pump.

The remedy I propose for this objectionable manner of the fitting of a steamer, is to require this pump to be located upon the main or tonnage deck, and that it have an independent boiler attached to it, located upon the main deck, or preferably upon the spar deck, in vessels having two or more decks; and that all passenger steamers be required to have this boiler ready for operation during the night, or during the prevalence of a fog.

RETARDING RAILWAY TRAINS.

From "Engineering."

It is a somewhat curious fact that, while during the past three years or so railway engineers on the continent have largely adopted the plan of retarding trains by means of counter-pressure exerted against the pistons of the locomotives, the subject has received practically little or no attention in this country. That the ordinary plan of retarding trains by the application of brake blocks to the wheels is at best but a very imperfect one, it is impossible to deny; and it appears to us to be well worthy of consideration whether it cannot, in many instances at all events, be replaced by a less crude system. On those lines, especially, which have long inclines down which it is not safe to run the trains without the application of some retarding power, a more perfect method of effecting that retardation than that at present in use appears to be particularly desirable. On such lines not only does the rapid wear of the brake blocks introduce an important item into the cost of working, but there is an absolute waste of power caused by the use of the brakes which it is most important should be avoided.

A theoretically perfect brake would be one which, while giving perfect command of the train, should act as a kind of reservoir of power, absorbing the energy or "work" stored in the moving train, when the latter has to be retarded, and giving it out again as required, when a start has to be made or the motion of the train accelerated. It is scarcely necessary that we should observe that these ends can never be fulfilled practically, even in the remotest degree, by any brake acting on the principle of effecting retardation by opposing frictional resistance. We say *practically*, because, as far as theoretical principles are concerned, the application of frictional resistance would cause the transformation of the energy absorbed into sensible heat, and this might *theoretically* be again converted into its equivalent number of foot-pounds of useful work; practically, however, as we have said, this could not, of course, be done. Practically, in fact, all work expended in overcoming such frictional resistance as is produced by brake blocks, is lost beyond all hope of recovery; and in searching after a more perfect method of retarding railway trains, those forms of apparatus in which friction alone is used as a retarding power must therefore be avoided. Our reasons for saying friction *alone* will appear presently.

Leaving, then, friction brakes out of the question, there are three principal methods of retarding trains, which have at various times occupied the attention of inventors. Thus, in the first place, it has been proposed that trains should be retarded by causing them—through the intervention of suitable gearing connected at pleasure with the wheels—to coil or compress springs, these springs being subsequently released, and caused to give out their stored-up power to the train when the latter had to be started. Some very wonderful patents have been taken out from brakes of this kind; but it is, we think, unnecessary that we should say more of these plans, as all engineers will at once see their impracticability. Next, we have the suggestions of those who propose to retard trains by causing them to pump air into a reservoir, the air thus compressed being in some cases employed to furnish a motive power for assisting in the starting of the train. We remember the designs of one inventor who, with a desperate disregard of the £ s. d. side of the question, proposed to fit a number of the carriages on each train with cylinders, pistons, connecting-rods, valve-gear, etc.; it being intended that when the train was to be stopped this machinery (the valve-gear being reversed) should be employed to pump air into a mammoth reservoir carried in a special carriage, and that when the train was to be started the compressed air should be admitted into the cylinders of the carriages again, and made to serve as a driving power as long as it would last. As an idea, this plan was, no doubt, all very nice; but we fear that its chances of ever getting beyond the ideal stage are exceedingly remote. Of the various plans which have been proposed for effecting the retardation of trains by expending their energy in effecting the compression of air, the most practical is probably that of Mr. De Bergue, which has been used on the Northern, the Eastern, and the Western railways of France, and also, we believe, on one of the Spanish lines. Mr. De Bergue's plan consists in reversing the engine when the train is to be retarded, and causing the pistons to pump air into a reservoir with which the locomotive is provided; this reservoir being fitted with a safety valve. To prevent dust from being drawn into the cylinders from the smokebox, the blast pipe is shut off from communication with the latter when the brake is in action, and air is admitted through a valve provided for the purpose. The results obtained with this brake on short inclines have, we understand, been very satisfactory; but we fear that for continued use on long inclines it would be unsuitable, as there would be danger of trouble arising from the heating of the pistons, packing, etc.; moreover the work expended in compressing the air is, in this instance, as much lost as if it had been employed in overcoming the frictional resistance opposed by brake blocks.

The third class of brakes of which we intend to speak here consists of those in which the counter-pressure of the steam against the pistons of the locomotive is employed as the retarding power. Of these the best are those of M. Le Chatelier, Herr von Landsee, and Herr Krauss, each of which possesses certain advantages of its own which entitle it to consideration, and, we may add, certain disadvantages. Herr Krauss's plan* consists of an arrangement by means of which the blast nozzle can be closed, and the steam admitted into the cylinders through the exhaust pipes, instead of in the ordinary way; the steam thus admitted being partly pumped back again into the boiler through the exhaust pipes, and partly discharged into the valve chests, and thence through a valve into the chimney. The slide valves, we should mention, are constructed so that they cannot be lifted from their places by the pressure of the steam on the under side. According to this plan the engine is not reversed when the retarding power is to be applied, but the course of the steam is merely changed in the manner we have just mentioned.

In order to point out more clearly the differences between this plan and those of M. Le Chatelier and Herr von Landsee, let us consider more minutely what goes on in the cylinder when Herr Krauss's brake is in action. For this purpose we shall confine our attention to one cylinder, and suppose the piston to be at the commencement of its forward stroke. In this case the hind end of the cylinder will be in communication with the valve chest, while the whole of the cylinder in front of the piston will be full of steam, being in communication with the boiler through the exhaust pipe. As the piston is forced forward by the motion of the engine and train, this steam will be pumped back again into the boiler, this action going on until the exhaust port closes, and compression begins—the compression continuing up to what, in the ordinary course of working, is the point of preadmission, when the front end of the cylinder being placed in communication with the valve chest, the compressed steam is discharged into the latter, from which a portion of it passes through the valve already mentioned, into the chimney. So far we have considered what goes on at the front end of the cylinder; let us now examine what occurs at the hind end during the forward stroke of the piston. During the first part of the stroke, the hind end of the cylinder being in communication with the valve chest, any steam that may be in the latter is expanded into the cylinder, and this action goes on until the piston arrives at what in the ordinary course of working would be the point of cut-off. At this point communication with the valve chest is closed, and the steam in the cylinder continues to expand until the hind end of the cylinder is placed in communication with the exhaust, when the steam rushes in and fills the space behind the piston, the supply being kept up until the end of the stroke. It will thus be seen that during the first portion of each stroke—or up to what under ordinary circumstances is the point of exhaust—the resistance to the motion of the piston consists of the full counter-pressure of the steam in front of it, assisted by a partial vacuum behind. During the subsequent portion of the stroke, however, the steam is, as we have shown, admitted behind the piston, and the resistance to the latter is then only that due to the difference between the pressure of this steam and that of the compressed steam in front of the piston. We have not yet had an opportunity of inspecting indicator diagrams taken from engines fitted with Herr Krauss's apparatus; but we should anticipate that the rise of pressure which will take place during the compression of the steam will in many instances be so great as to be objectionable. If this is the case, however, the objection might be readily overcome by fitting a small spring-loaded valve, opening outwards, to each cylinder cover, these valves being of course so loaded that they would not open until the ordinary working pressure of the steam had been considerably exceeded. It will be noticed from the description we have given that Herr Krauss's is not a "regenerative" brake, or in other words, the work done by the pistons in retarding the train is not stored up for subsequent use. In other respects we consider the arrangement a good one.

* See "Engineering," p. 475, 1868.

The steam-repression brake of Herr von Landsee in some respects resembles in its action that of Herr Krauss's; but the mode in which the results are obtained is different. Like Herr Krauss, Herr von Landsee does not reverse the engine, when the brake is to be applied; but he closes the exhaust pipe, places the link motion nearly or quite in mid-gear, and admits the steam against the piston for nearly the whole stroke by means of an auxiliary slide valve, worked by an eccentric which is set without any angular advance. The employment of an additional valve, eccentric, etc., for each cylinder appears to us to be an important objection to Herr von Landsee's plan, and we must confess that we cannot at present see what advantages he can gain by his system which will compensate for the additional complication. We may remark here that in both Herr Krauss's and Herr von Landsee's plans, the cylinders are lubricated by the steam in the same manner as during ordinary working, so that there is no danger of overheating, cutting, etc.

We now come to M. Le Chatelier's apparatus, which has, during the past three years, come into extensive use in France, more than five hundred locomotives being fitted with it on the Paris, Lyons and Mediterranean line alone. The apparatus has also been applied to a large number of engines on the Northern railway of Spain and other Continental lines. M. Le Chatelier's apparatus may be simply described as an arrangement for enabling a locomotive to be reversed whilst running without danger of damaging the cylinders, valve-faces, etc., by dust or grit drawn in through the exhaust pipe from the smokebox. As fitted to the engines on the Paris and Lyons railway the apparatus consists of a closed copper box divided into three compartments, two of these compartments being respectively connected with the steam and water spaces of the boiler by suitable pipes, while the third compartment is separated from the two others by a partition having formed in it ports covered by small slide valves. By means of these valves steam and water can be admitted in regulated quantities when required into the third compartment, from which the mixture is conducted by a pipe furnished with branches to the exhaust pipes from the two cylinders. When the engine is reversed, the mixture of water and steam is admitted to the exhaust pipes, a portion of this mixture escaping through the exhaust nozzle, and preventing the ingress of air from the smokebox, while the remainder is pumped by the action of the pistons into the boiler. Recent experiments made on the incline at Etampes, on the Paris and Orleans railway, by MM. Forquenot and Le Chatelier, have shown that the admission of water alone, from the boiler into the exhaust pipes, fully serves all the desired ends, without the admixture of steam. When the water is admitted to the exhaust passages in this way the sudden relief of pressure causes it to be diffused as a fine mist, a portion being vaporised and escaping as steam through the exhaust nozzle, whilst the remainder enters the cylinders, and not only lubricates them and the valve-faces, but is evaporated by the heat developed by the friction, and is pumped back as steam into the boiler. The experiments with the apparatus have, in fact, shown that when an incline is being descended, the apparatus being in use, the pressure in the boiler increases rapidly, while there is no heating of the piston packing or valve-faces, and, the pumping of air into the boiler being prevented, the action of the injectors is not interfered with. This latter is an important point now that these instruments are so generally used for feeding locomotive boilers; and to ensure it, care should always be taken in using M. Le Chatelier's apparatus that there is a small escape of steam from the exhaust nozzle.

The retarding power obtained by reversing an engine, may be diminished or increased by placing the valve motion nearer to or further from mid-gear, and to enable this adjustment, and also the reversal to be effected with ease and safety while the engine is running the locomotives on the Paris and Lyons railway, fitted with M. Le Chatelier's apparatus, have been also provided with screw reversing gear, similar to that which we illustrate on page 300 of our third volume. In any case, however, the retarding power which M. Le Chatelier's arrangement is capable of affording, is less than that given by the plans of Herr Krauss and Herr Landsee. This will be evident if we consider what goes on during a stroke of the piston when an engine is reversed; and let us suppose for example that, as before, the piston is just commencing its forward stroke. In this case, the engine being reversed, the hind end of the cylinder will for a short portion of the stroke (equal to the period of preadmission in ordinary working) be in communication with the valve chest, and steam will thus be admitted. After the steam port is closed, there will be a period of expansion lasting until the piston arrives at the point which, if the engine was not reversed, would correspond to the commencement of the exhaustion during the backward stroke of the piston. On this point being reached the hind end of the cylinder will be placed in communication with the exhaust pipe, and the mixture of steam and water will thus be admitted from the latter into the cylinder. This admission will continue up to the end of the stroke. During the early part of the return stroke, the communication between the hind end of the cylinder and the exhaust continues open, so that a portion of the vapor admitted is forced back into the exhaust pipe again; but on the piston reaching the point which corresponds in ordinary working to the commencement of the exhaustion during the forward stroke, the communication between the hind end of the cylinder and the exhaust is shut off, and the vapor contained in the cylinder is compressed by the piston. Finally, when the piston reaches the point corresponding to the cut-off of the steam during the forward stroke, when the engine is not reversed, the valve uncovers the steam port leading to the hind end of the cylinder, and the full pressure of the steam is admitted against the piston during the remainder of its stroke, the steam thus admitted, together with the vapor already in the cylinder, being eventually forced back again into the boiler.

Briefly stated, then, the difference between the action of M. Le Chatelier's arrangement and that of Herr Krauss is this—that in the former the steam is admitted against the piston during a period corresponding to that of the admission of steam behind the piston, if the latter was moving in the opposite direction, and the engine was not reversed; while, according to Herr Krauss's plan, the period of admission of the steam against the piston corresponds to the duration of the exhaustion in ordinary working. At slow speeds the difference in the retarding powers of the two plans is perhaps not so very great, but when the engine is running fast the power of M. Le Chatelier's system is considerably diminished as compared with Herr Krauss's, the comparatively slow opening of the steam ports by the slide valve preventing the full pressure from being maintained against the piston, in the former case, for anything like the theoretical distance.

The want of sufficient power is, we consider, the only real objection to M. Le Chatelier's system; and there are very many circumstances in which even this objection does not apply. According to experiments made by M. Guebhard, of the Eastern railway of France, a retarding power can be obtained by M. Le Chatelier's arrangement equal to about 40 per cent. of the full tractive power of the engine; and there are very many cases in which this amount of retarding power will prove amply sufficient. In one respect M. Le Chatelier's system has a decided advantage over Herr Krauss's or Herr von Landsee's, and that consists in its turning to useful account a portion of the work performed by the pistons. The water admitted into the cylinders takes up the heat generated by the friction of the pistons, etc., and, being converted into steam, carries this heat back into the boiler. At first sight this may appear a small matter, but the experiments made by M. Ricour, on the Northern railway of Spain, have shown that in some instances the heat thus carried back during the running of one kilometre with the apparatus in action is equal to that generated by the combustion of 2.2 kilogrammes of coal, or about $7\frac{5}{8}$ lb. per mile. M. Le Chatelier's apparatus may therefore lay fair claim to belonging to the class of "regenerative" brakes.

The present article has already run to such a length that we must leave untouched many points connected with the subject on which we have been writing, and must conclude by saying a few words concerning an objection that has been often raised against the employment of any of the plans we have described. This objection is that the employment of all "piston brakes," if we may be allowed the expression, throws injurious strain upon the working parts of the engines. This objection we believe to be entirely without foundation so long as the resistance opposed to the motion of the pistons is not so great as to cause slipping of the wheels. Slipping is no doubt injurious in many ways; but we believe that it is very nearly as injurious if caused by the application of brake blocks as if caused by opposing resistances to the pistons. In any case the strain which can be thrown upon the connecting rods, etc., is limited by the adhesion of the driving or coupled wheels, and we fail to see that these strains can do more injury to the various parts when tending to retard the motion of the engine than when employed for the opposite purpose.

ROADS.

In an article on this subject, in the "New Jersey Courier," Mr. E. Sherman Gould, C. E., after pointing out the importance of *good* highways as feeders to railways, gives the following results of experiments and practice in France, which, though not modern, are standard and timely:—

"According to a most instructive tract by Gen. Sir John F. Burgoyne on the maintenance of macadamised roads, there were in France in 1835 some 45,000 miles of high roads, over which the yearly draft of merchandise was effected at an expense of about ninety millions of dollars. The French engineers calculated that at least one-third of this amount or thirty millions of dollars might be saved to the public by maintaining the roads in the best possible condition, and that not only at no additional cost, but with a positive reduction of the then annual expense of the maintenance. Now the French engineers are not subject to slips in their calculations, and it therefore becomes a most profitable study to investigate the means by which they proposed to accomplish this astonishing result. Briefly, they consisted first in putting the roads in perfect order, and then keeping them so. The system previously pursued had been to use the roads with few or no repairs up to the last moment it was possible to drag a vehicle over them, and then rebuild them entirely, preserving all the elements, such as bad drainage and bad foundations, which had already hastened their destruction. To accomplish the improved state of things, every attention was paid to the formation of the road-bed, and it was then subjected to a most minute and unremitting surveillance by an organized corps; every inequality of surface was filled up as soon as it occurred, and all waste matter was regularly removed, preferably as dust, with brooms in dry weather, but sometimes also as mud, in wet weather, by hoes and hand-scrapers, the horse-scraper being abolished, as battering the smooth surface. It was found that by this system of constant patching and sweeping, an immense saving of material was effected, since no more was put down than was absolutely required.

As an example of how far these calculations were verified, Gen. Burgoyne instances the case of the post road between the towns of Tours and Caen, a length of about 150 miles, which in 1836 was announced in an official report as being in so bad a state, that without a special credit of ten thousand dollars and a great additional provision of materials, there was danger that it would become impassable. In January, 1837, its reconstruction was commenced. In August, 1838, it was reported to be in a very good and constantly improving state. In 1834 the mail had always required five horses, and in one year eleven were lost by overwork. In 1837 four to five horses were required. In 1838 the number of horses was reduced to three. In 1841 only two were required of middling quality, and none were lost from over-work. In 1839 a lighter class of conveyances than that formerly employed was introduced, carrying nine passengers, *drawn by one horse at between seven and eight miles an hour.* The expenses of maintenance in 1837 were for materials $2,900; labor $2,500; total $5,400. In 1841 they were for materials $810; for labor $2,200; total $3,010. It will be thus seen that while the expense for labor remained nearly the same, the cost for materials diminished more than two-thirds.

The improved roads of France are all, or nearly all, macadamised. Their width varies according to their tonnage. The portion devoted to vehicles is never less than sixteen (16) feet. Ditches are dug on each side, and when necessary the road-bed is underdrained. The surface is slightly rounded, and but slightly, for it is important that vehicles should be able to stand upright on any part of it, so as to discourage the tendency to seek the center only, and produce a more even wear. As far as possible, the grades are kept between the limits at which water will run, and at which a vehicle will stand without running down hill by its own weight; when practicable not less than the former nor greater than the latter. The road-bed being properly prepared, it is covered with about six inches of broken stones, of such a size as to pass freely through a ring $2\frac{1}{2}$ inches in diameter, the stone being very carefully selected, chiefly with regard to its *toughness*, basalts and granites being the most esteemed. It is then heavily rolled, with rollers ranging from two to five tons in weight, the operation being repeated until the surface is compressed into a smooth, solid crust, gravel being slightly sprinkled over the road while in process of rolling. The road being thus brought to the highest degree of hardness and smoothness, *is never suffered to deteriorate.* This is the secret at once of its great carrying efficiency, and the economy of its repairs. The same reduction of shock and friction which enables a team to draw a heavy load swiftly over the surface, diminishes in a rapidly increasing proportion, its wear and tear. On the other hand, the incessant patching of the road wherever the uniformity of the surface is in the slightest degree impaired, reduces to a minimum the interference with rapid traveling, the amount of damage sustained at any given moment by the road and the quantity of material used in its maintenance, for the rough spots are always few and small, the little hollows formed in the road are never left to gain ground by wear and water, and not a pound of material is wasted.

Such are the leading principles which govern road-making abroad, and such we cannot but think the results to which our efforts in this country should tend. It is not, of course, to be hoped that, unaided as we are by government interference, we can attain to this degree of success in our roads, but we may rest assured that the nearer we approach to the path which the experience of older countries indicates, the nearer we will attain to the desiderata of a *maximum efficiency and a minimum expense.*

RIVERSIDE CONSTRUCTION.

From a paper by Mr. Rowland Plumbe, A.R.I.B.A., read before the Architectural Association.

The author said that he would confine his remarks principally to the description of a riverside building which had lately been erected, and to which his special attention had been directed. The building was of the warehouse description, of a great height, and designed for the storage of heavy goods, the floors being constructed to sustain five cwt. per superficial foot. Not only was there a frontage to the river, but the return wall, for a distance of about 150 ft., formed the side of a dock, part being built over and part forming a wharf wall. Large and lofty cellarage was required under the whole, the floor line of which was to be nearly 12 ft. under the highest water level. The tide rose and fell against the whole length of the front and side walls to a height of from 10 ft. to 13 ft. The special requirements under such cases are, first, to secure a thoroughly good foundation, and, secondly, to prevent the water from entering the cellars. In describing the means of obtaining these results, the author confined his attention to such measures as he had either seen taken or recommended by practical men, or had himself directed to be carried out, avoiding all recommendations found in books as being of less value than a simple description of the means used in a certain case with great success.

River Wall.—The first question to be determined in building the river wall is, whether to construct a dam or to build the work as the tide recedes. Wherever the tides will allow of the construction of buildings without a dam, the question is practically settled by the much smaller cost entailed, and the shorter time required for the execution of the work. Assuming, then, that the work is to be constructed without a dam (*i. e.*, by tide work), the water must be pumped out of the trenches immediately the excavations are lower than the mud bank of the river. A convenient place must be found for the engine, which should be of from eight to twelve horse power, and the pump should be capable of throwing out about 1,200 gallons per minute. The position of the engine will depend to a great extent on the position chosen for the sump, which should be placed as centrally as possible. The pump and engine being ready for working, the first excavation made will be for this sump, which is a well or receiver for all the water to be raised from the trenches, than which it should be sunk a few feet deeper. The trenches are then taken down to the requisite depth in lengths of from 15 ft. to 20 ft.; drain pipes of suitable diameter (say 6 in.) are laid along the trench, and when the water has been pumped out the concrete is filled in in layers to the required depth, suspending operations, of course, at each rise of the tide. The next sections can then be excavated on either side. The ends of the pipes laid along the bottoms of the trenches are now opened, to get rid of the water which has accumulated in them. As additional sections of the trenches are excavated, other lengths of pipes are connected with the former ones, the concrete is filled in, and the whole length of the foundations is easily and efficiently drained. It is important that the sump-hole should be excavated outside the trench. It should always be carefully filled up with fine Portland cement concrete when done with. The sides of the excavations will have to be close planked on each side, and carefully shored, and it is important that the sheeting should be left in the excavation when the concrete is filled in, the sides of the trenches not being sufficiently firm to hold the concrete until it has set, especially when disturbed by the drawing out of the planking. A necessary precaution in filling in and ramming is to protect the footings of the wall with concrete, instead of filling in with ordinary material, which is liable to be washed away by the scour of the river. As a rule it will be necessary to excavate until the sharp clean ballast is reached, and in any case it would be prudent to go as low as the bed of the river at its deepest part opposite the site of the building. Some architects advocate the forming of a foundation on a staging resting on piles driven to a great depth. Recent experience has, however, shown that this system is certainly not preferable to concreting, especially for heavy buildings, as the scour of the river will frequently so undermine the earth against the piles that all lateral support is taken away. Added to to this there are always chances of imperfectly driven piles and decaying timber rendering this form of foundation one of great risk. The concrete used should be a quick and hard-setting material. The author had found fresh burnt, finely ground Portland cement, especially made for hydraulic purposes, and mixed with clean river ballast in the proportion of one of the former to seven of the latter, to answer admirably. It should not be thrown from a greater height than necessary, nor should large quantities be thrown in at a time, as in that case the whole bed becomes jarred, and the process of setting is interfered with. Where practicable, a strong gang of men working alongside and throwing in the concrete with the spade as it is mixed, will obtain the strongest foundation. It frequently happens that the spring and return waters accumulate so fast that it is necessary to have the proportion of cement increased; the author had seen good work produced in such cases by having the concrete mixed dry, and again mixed with the water in the trenches as it was thrown in. It is always well to have a few sacks of cement ready to throw into the trenches when there is a danger of the cement being washed out of the ballast by the rapid ingress of the water.

The author next proceeded to describe a formula for ascertaining the thickness of a section of a river wall of given height to resist a given pressure of water; but any formulæ of this kind are of little value, because when the superincumbent walls are built, and the weight of the same and of the respective floors bearing upon them came on the top of the river wall, perfect stability would be obtained with a much less thickness than would otherwise be necessary. A less average thickness than six bricks would not adequately suffice to keep out the water and resist the impact of river craft. Even when of this thickness special precautions must be taken to guard against the first contingency. The wall should be gradually sloped up with footings from the concrete, and should have a batter on the river side of about one inch to a foot. The material and build of the wall are of the highest importance. In the wall referred to by the author, the hardest and closest textured stocks procurable were used, faced with Staffordshire blue bricks, not dressed, but of the ordinary building quality, built in Portland cement, and pointed with neat cement shortly after completion with an ironed joint, bevelled so as not to retain the water more than possible. In building the wall itself too much care cannot be taken in trying to make it as much like one mass as possible, and in seeing that every joint is thoroughly flushed up. Every course should be grouted, and the cement used with as little sand as possible, and never in more than equal proportions. In cases of this kind it is well not to trust to an ordinary workman to mix the cement. A banquer should be used, and the cement should be accurately measured, as also the sand, the latter (however clean in appearance) being carefully washed for use. No river wall is likely to keep back the water, in the construction of which imperfectly washed sand has been used, or in which a larger proportion of sand than cement has been employed. Roman cement should be carefully avoided in such cases, as its setting properties require more care than can be depended upon on the part of the ordinary run of bricklayers.

In order to render water-tight the wall constructed by the author, he had used a water-proof material built *in* its center, so as to be free from injury or decay. The wall was built in old English bond, and in its center a space of about $1\frac{1}{2}$ in. was kept between the stretching courses. This place was filled in with asphalte, and the heading courses were likewise bedded in asphalte. The great difficulty in the way of successfully applying asphalte in such a position is to keep the work sufficiently free from water until the asphhalte has cooled and set, for if the least steam or vapor is generated, it is liable to render the asphalte porous and spongy. A good water-resisting surface could be obtained by building up the center of the wall in the same manner, but using the cement quite neat, in conjunction with hard Staffordshire blue bricks. To ensure a waterproof wall the cement must really be used neat, and must be sufficiently air slaked as not to blow in the setting. The careful washing and cleansing of the bed of the work from the mud deposit after each tide has receded, must on no account be overlooked. Particularly must this deposit be removed from the racking back or toothed edges of that section of the wall which is above the other. Even a thin bed of mud would be sufficient to destroy the continuity of the cement work, and leakage would be the result. As an extra precaution it would be as well to point the inside face of the wall in neat cement, well raking out the joints and pointing with a flat trowelled joint for limewhiting. Although stock brickwork in cement is mostly used for river walls, certain non-porous stones and granite are sometimes used, but even with these materials there will always be a tendency for the water to find its way through the joints. The gault bricks, lately so largely used for sewer construction, are admirably adapted for river walls, provided they are kept thoroughly soaked in water before being used, for there is a danger of the cement not thoroughly taking to this kind of brick on account of its non-porous and fine texture.

The wall having been built in sections of from 15 ft. to 20 ft., the tidal water as it advances and recedes completely surrounds the whole wall at the same level during the whole time of its construction, and consequently it has at all times been free from the pressure of the tides. But in order that the inside banks may be cleared away and the building proceeded with, it will be necessary to shut out the water. Sufficient time must be given for the work to thoroughly set, and as a rule, it is better for a story or two of the superincumbent walls to be built over the river walls before shutting out the water, as the additional weight is a great help to stability. Six weeks or two months having been given from the building of the last section, and as much of the upper walls as possible having been built, the whole of the walls, every few feet apart, should be shored with whaling and wall pieces, and the wedges driven hand-tight, so as to resist any outward pressure towards the inside without forcing the wall outwards. This having been done, the openings should be carefully bricked up in neat cement, a tide valve for the exit of the spring and other water inserted, and the chief part of the river wall will have been completed. Although the tidal water comes up the face of the wall nearly to the level of the floor above the basement, it will be necessary to have a damp course slightly below the level of the basement floor. This can be of asphalte or of some of the glazed stoneware damp courses now used, provided that they are not perforated or so highly glazed as to prevent the cement from properly adhering to the joints and beds. A good material of this kind would effectually prevent the water from rising through the wall when under the greatest pressure of the highest tide.

As there is a liability of a greater amount of wear and tear at about the level of the highest water mark, and as it is highly desirable to have a good foundation for the walls supporting the upper floors, and a foundation of such a nature as to resist the dampness that would constantly be liable to arise from capillary attraction, it is usual to put a granite kerb at about this level. This should be in as long lengths as possible, joggle-jointed, the bed being at least 12 in. deep. For the protection of the wall from river craft, timber fender piles should be placed about 8 ft. apart. They are usually of fir, and should be Kyanised or Burnettised, or undergo some similar process. They should be 12 in. square, and so fixed to the wall as not to injure it in the event of great strains or sudden shocks being given to them. It is usual to bolt them through the wall, but where possible this mode of fixture should be avoided. A strong cast iron shoe, with a suitable flange, built into the wall to receive the bottom of the pile, and a head of a similar character, with a similar flange, both having bolt-holes, and both being secured to the piles with strong coach screws, will be found much safer. Of course, in wharf walls having no superstructure there will be no alternative but to bolt through the walls.

In designing river walls especial care should be taken to avoid projecting surfaces. Any projections or indents render the barges or other craft alongside liable to be caught by them as the tide rises, and held there un til the water rises over and sinks them, or until the wall itself was lifted or shaken. To prevent such occurrences the bolt-heads of the piles were frequently furnished with flat circular cast iron roses, with holes sunk for the bolt heads, but even this slight projection is objectionable. No projecting kerb should be put along the edge of a wharf wall, for it is sure to be lifted by the rising of the craft.

Wharf Walls.—A wharf wall with no superstructure upon it, and backed up by the bank will, if about six bricks thick, generally be found of sufficient strength. But where cellars or arched vaults are required, it is necessary to add to its strength, partly to resist the thrust of the arch, and partly to strengthen the wall beyond any fear of accident. The author had done this by building up piers at the back, and springing segmental arches upon them in a longitudinal direction, immediately over which the skewback of the vault was formed. In such instances it is always well to cover the backs of the arches with asphalte, laid on in two thicknesses, and with a slight fall towards the river, so that any water percolating through the pitching might find its way out down the ouside face of the wall.

Inland Walls.—On the land side, in works of this nature, provision has to be made against a permanent pressure of water which accumulates from the landsprings and other courses which, in such situations, always flowed towards the river. These being intercepted by the buildings alongside the river, it frequently happens that an outlet does not occur for some considerable distance, and where this is the case the danger of the water finding its way into the building is very great. As a rule, any system of drainage below high water mark had better be avoided, as depending upon receiving tanks, penstocks, tide valves, and other costly and uncertain arrangements. Any self-acting apparatus is likely to get out of order, and any machinery dependent on manual labor may at any time fail through neglect. In either case the result would be the complete flooding of the basement. For this reason all water should be kept entirely out of the basement, but for this no ordinary precautions are needed. More failures occur in the inland walls in respect of keeping out the water than in the river walls. The concrete, for such walls should be composed as before mentioned, or, if not, of Portland cement, at least of hydraulic lime. The walls should be, as a rule, at least four bricks thick, even though not required to carry the superstructure. They should be built in cement and of hard stocks, in the manner described for the river wall, and a water-resisting medium of the same nature, as before described, should be built up in the center of the wall. The wall on the outside should be pointed with a bevelled trowelled joint, or, better still, should be rendered in neat Portland cement. This last precaution will generally prove the cheapest and most efficacious in the long run, although somewhat expensive at first. A damp course, as before spoken of, will be most necessary, or the water will rise on the inside face of the wall, even from the concrete upwards, as, at extremely high tides, there may sometimes be at the top of the concrete a pressure of over 1,000 lb. per ft. of water. A lining of puddle, 12 in. thick, packed behind the wall as it rises from the foundations, in lieu of the ordinary filling in, will be most useful in keeping the water away from the wall. For some classes of goods it is desirable to have wooden floors in the cellars. When this is the case, the basement should be made lofty enough to allow of such a floor being put in and the requisite space for ventilation being provided under it.

The Floor.—Perhaps the floor is the most important feature for keeping out the water. In forming a judgment of the various steps to be taken to render the basement waterproof, it may be considered as a huge tank, which must be made entirely and at all points waterproof. Any waterproof coating on the inside (which could easily be got at) would, if put upon a sufficiently firm backing, effect the purpose of holding water. But to keep out water, the proper place to put the resisting material would be on the outside of the wall, the backing being inside. By the description of the construction of the side walls, it will be seen that this has been so far effected. In the building of the side walls the first precaution towards keeping the water from rising up through the floor will be to break the straight joint at the juncture of the floor and walls. Every alternate course of the brickwork below the floor level should be built out at least a quarter of a brick for a height of eight or nine courses. The brick piers for the supports of the floors should be similarly constructed. The first layer of the floor should be puddle, not less than 18 in. thick;

this being sure to drive the water to the walls, the value of the toothings will be manifest. The puddle should be well rammed into these toothings. The next layer should be formed of asphalte, a thin layer of concrete (say 4 in. thick) being laid over the puddle to receive it. The asphalte should be laid on in at least two thicknesses, and a row of hard bricks or gault tiles should be bedded against the walls—and especially the piers—until a good firm hold has been obtained of the brickwork. The asphalte should be carefully watched, and, if possible, left till a high tide has tried its resisting powers. Wherever the least defect occurs, a gault tile laid over it and another layer of asphalte laid over that will probably stop it. At all events, the asphalte must be laid on layer after layer until it has conquered the water, and it should also be carefully trowelled against the upright work of the piers and walls as high as the next layer, which is formed of Portland cement and fine ballast, in the proportions of one to five, and laid on 12 in. thick, the upper 3 in. being grouted to form a floor or to receive any floor that may be put on it. This sets like one solid mass of stone, and is most valuable in keeping the asphalte in its place.

The asphalte is not put on the surface because the author had found, both in upright and floor work, that, however efficacious it is to resist mere dampness, owing to its elastic nature, it parts from its backing and blows and cracks wherever there is even a slight pressure of water, and when once this takes place, it is powerless to resist the ingress of water. Where, however, it is confined between hard substances, such as those used for the flooring, or between a brick wall, it cannot move, and retains its water-resisting qualities. The interior of the walls should be coated with asphalte, and if not found sufficiently dry to admit of that operation, the joints should be raked out, the surface hacked, and a lining of two thicknesses of gault tiles bedded in neat Portland cement, finished with a trowelled surface, should be applied. This lining should go down to the edging of the gault tiles and asphalte, before mentioned, and the asphalte should be turned up against it. The cement should be the best obtainable, and it should be turned out of the bags and spread out for twenty-four hours before use to avoid the chance of blowing in the setting. If the tiles and cement are carefully applied by plasterers, the walls will be rendered waterproof. Mr. Plumbe, in conclusion, said the precautions he had pointed out were nearly all necessary for the successful execution of the description of work referred to, and he could recommend them as having practically tested them.

AIR-SURFACE CONDENSERS.

THEIR PRINCIPLES AND PROPORTIONS.

From "Engineering."

When a tube heated internally by steam or other means is exposed to the air, it loses heat in two ways, namely, by radiation and by convexion, the amount of heat lost by each of these means being subject to considerable variation, according to the temperature of the tube itself, the temperature of the air in contact with it, the temperature of surrounding objects, and other circumstances. At low temperatures the loss by radiation may be taken as sensibly proportionate to the difference between the temperatures of the emitting and receiving bodies; but at high temperatures, and with great differences of temperature, this law does not hold good. The loss of heat by convexion, or by contact of the air, does not vary directly as the difference of temperature between the heated body and the air, but becomes proportionately greater as that difference is increased. The laws which govern the cooling of heated bodies exposed to the air are, in fact, somewhat complex, and we shall not attempt to enter fully into their consideration here, but shall merely apply to the case under consideration the data which have been obtained by reliable experiments.

The most valuable researches on the cooling of heated bodies exposed to the air are those of Dulong, who has deduced from his experiments some excellent, though somewhat complicated, formulæ for calculating the loss of heat under different conditions. According to the experiments of Dulong, a horizontal pipe, 2 in. in diameter, containing steam at atmospheric pressure, and freely exposed to air at a temperature of about 57°, would be subject to a loss of heat sufficient to condense .34 lb. of steam of atmospheric pressure for each square foot of exposed surface per hour. If the pipe were filled with steam at a pressure of 100 lb. per sq. in., the temperature of the external air remaining the same, the loss of heat would be sufficient to condense about 0.8 lb. per square foot of surface per hour. These results agree very closely with those obtained in the course of ordinary practice by Messrs. Perkins, who have had very considerable experience in heating by steam pipes. Messrs. Perkins have found that in the case of pipes, charged with steam at a pressure of 100 lb. per sq. in., about 100 sq. ft. of exposed surface are requisite to condense per hour the steam produced by the evaporation of a cubic foot of water, whilst, when the steam in the pipes is of atmospheric pressure, about 150 square feet of surface are required to produce the same result. The amounts of steam condensed under the two circumstances were thus 0.625 lb. and 0.417 lb. per sq. ft. per hour, quantities which agree very fairly with those given by the researches of Dulong. These results, it must be borne in mind, are due to the combined losses by radiation and contact of air; but in the case of a surface condenser, consisting of tubes surrounded by steam and traversed by currents of air, the loss of heat by radiation would be vastly reduced, the cooling effect being almost entirely due to the contact of air alone. Under these circumstances the value of the cooling surface would be diminished to about one-half that of surface freely exposed to the air, and instead of each square foot being capable of condensing, per hour, about $\frac{1}{3}$ lb. of steam of atmospheric pressure, it would only be capable of condensing little more than half that quantity. On the other hand, the steam discharged into the condenser will, in all cases, have a temperature higher than that due to steam at atmospheric pressure, and this excess of temperature, combined with the rapid circulation of the air through the tubes, caused by a fan or other contrivance, will, to some extent, increase the efficiency of the condensing surface; and taking all these facts into consideration, we may, we think, fairly estimate the value of such tube surface, as about equal to that of freely exposed surface heated by steam at atmospheric pressure, each square foot being capable of condensing, say, $\frac{1}{3}$ lb. of steam per hour.

Taking this fact as our starting point, let us next ascertain the dimensions of an air-surface condenser, suitable for such an engine as that mentioned by our correspondent. It is proposed that the boiler of this engine should have 160 sq. ft. of heating surface, and this surface is estimated to be capable of evaporating 5 lb. of water per square foot per hour. The total evaporation would thus be $160 \times 5 = 800$ lb. of water per hour; and, supposing the whole of the steam produced to be used by the engine, the condenser would require to have $800 \times 3 = 2,400$ sq. ft. of surface. Again, if we suppose the condenser to be traversed by tubes $\frac{3}{4}$ in. in diameter inside, we should have almost exactly $\frac{1}{5}$th of a sq. ft. of cooling surface for each foot run of this tubing; and to obtain the 2,400 sq. ft. of surface, there would have to be 12,000 ft. run of tubing in all. If the tubes were 6 ft. long, 2,000 of them would thus be required, and these could probably be stowed within a casing about 4 ft. 6 in. in diameter; or if 3,000 tubes, 4 ft. long, were employed to make up the surface, they could be arranged within a casing having a diameter of about 5 ft. 6 in. In estimating these dimensions of the casing, we have supposed the distances between the tubes to be $\frac{1}{4}$ in. The weight of the condenser would be nearly, or quite, three tons.

Next, let us calculate the quantity of air which it would be necessary to supply to the condenser in order to carry off the heat abstracted by the steam; and in making this calculation we may fairly assume that the steam would be discharged into the condenser at a pressure of about 15 lb. per sq. in. above the atmosphere. The total heat of steam at this pressure is 1,190°, and to reduce a pound of such steam to water at a temperature of 212°, there would have to be abstracted $1,190-212 = 978$ pound-degrees, or units of heat. Multiplying this number by 800, the number of pounds of steam to be condensed per hour, we get $800 \times 978 = 782,400$ as the number of units of heat to be taken up per hour by the air passed through the condenser. Now, the specific heat of air, at the ordinary atmospheric pressure, is to that of water as 0.238 to 1, and a unit, or pound-degree, of heat will therefore raise a pound of air $\frac{1}{0.238} =$ 4.2°. If we assume that the air enters the condenser at a temperature of 60°, and leaves it at 120°, its temperature being thus raised 60°, the quantity of air required will be, according to the facts already stated, $= \frac{782,400 \times 4.2}{60} = 55,721.5$ lb. of air per hour. At a temperature of 63°, the weight of air is 0.0761 lb. per c. ft., and the above weight would thus correspond to $\frac{55,721.5}{0.0761} = 732,$-213 cubic feet per hour.

We now come to another point, namely, the power requisite to furnish this supply of air to the condenser. If we suppose the latter to contain 2,000$\frac{3}{4}$ in. tubes, 6 ft. long, these tubes will have a combined sectional area of 6.138 sq. ft., and the velocity at which they would be traversed by the air would be $\frac{732,213}{6.138 \times 60 \times 60} = 33.3$ ft. per second. To produce a flow of this velocity there would be required, according to the ordinary rules for calculating the flow of air, and supposing no resistances from friction, a difference of pressure at the two ends of the condenser equal to a head of about 0.00916 lb. per sq. in. Again, in the case of a $\frac{3}{4}$ in. pipe a foot long, there is required a difference of pressure of 0.000073 lb. per sq. in. at the two ends, in order to overcome the frictional resistances due to the transmission of one cubic foot of air per minute; and these resistances increase directly as the length of the pipe, and as the square of the quantity of air passed through it. In the condenser with 2,000 tubes, each tube would have to transmit $\frac{732,213}{2,000 \times 60} = 6.1017$, or, say, 6.1 cubic feet per minute, and, as the pipes are 6 ft. long, the difference of pressure at the two ends, to overcome the frictional resistances due to the transmission of this quantity, would be $6.1^2 \times 6 \times 0.000073 = 0.01629798$, or, say, 0.0163 lb. per sq, in. Adding this pressure to that formerly obtained as necessary to give the required velocity of flow, we get $0.0163 + 0.00916 = 0.02546$ lb. as the difference between the pressures at the two ends of the condenser tubes, requisite in order that they may transmit the necessary quantity of air.

This difference of pressure of 0.02546 lb. per sq. in. is the pressure against which the fan—or other blowing apparatus employed to supply air to the condenser—would have to deliver the air; and the net-work done by the fan will be the same as if the whole weight of air was raised to a height equal to that of a column of air of uniform density which would give the same pressure per sq. in. on its base as that against which the fan has to deliver. At the temperature of 62° the height of a column of air giving a pressure of 1 lb. per sq. in. on its base, is 1,892 ft., and the height corresponding to a pressure of 0.02546 lb. per sq. in. is thus $1,892 \times 0.02546 = 48.17032$, or, say, 48.2 ft. The total weight of air passed through the condenser per hour being 55,721.5 lb., the work to be done by the fan will amount to $\frac{55,721.5 \times 48.2}{60} = 44.762.9$ ft.-lb. per min. This, it must be remembered, is the net amount of work performed by the fan, as measured by the quantity of air delivered, and it will form, probably, not more than 60 per cent. of the power required to drive the fan, and consequently taken from the engine. Taking the effective duty of the fan as equal to 60 per cent. of the power applied to it, we should thus have $\frac{44,763 \times 100}{60} = 74,605$ ft.-lb. of work per minute, or 2.26 horse power absorbed in driving the fan, an amount probably equal to quite one-eighth of the total indicated power developed by the engine.

If, in place of 2,000 tubes 6 ft. long, 3,000 tubes 4 ft. long were used in the condenser, the power required to work the fan would no doubt be very considerably reduced, but it is unnecessary that we should do more than point out this fact here. Quite apart from the power absorbed in driving the fan the air-surface condenser is rendered unfit for application to a portable engine by reason of its cumbrousness, and there are really but very few situations in which it can be applied to engines of any class with advantage. So far as we are aware the only method of increasing the efficiency of condensers of this class is by moistening the air either by the injection of spray or other means, or by causing the cooling surface to be traversed by a thin film of water, as has been successfully done in some instances.

RESISTANCE OF ARMOR PLATES.

From a paper by Wm. Fairbairn, C. E., LL. D., F. R. S., read before the Institute of Naval Architects, March 18, 1869, and the ensuing discussion.

After a brief statement of the progress of marine iron constructions from 1836 to the present time, the paper stated that shortly after the appointment of the Iron-plate Committee, guns of different calibers were employed in the experiments, from the wall piece .87 in. bore and 5½ oz. of shot, to the 600-pounder breech-loader. The experiments commenced in May, 1861, with the wall piece and the smaller description of guns, and finished with the more powerful description of ordnance in 1864, when the committee was dissolved. During the continuance of the gun experiments, it was considered necessary that a similar class of experiments by statical pressure should be conducted on the same plates and targets, previously experimented upon in their resistance to impact by shot, the object being to determine the law of resistance of armor plates, and to establish formulæ for the guidance of the artillerist and engineer. Experiments were also made on shearing, tension, compression, &c., and the results obtained showed the density, tenacity, &c., of four different specimens—cut from the armor plate, one of which was of steel. The first series of experiments was instituted to ascertain the tenacity, elasticity and ductility of the plates from different makers, and to ascertain what changes and improvements were required to give the maximum power of resistance. The result of these experiments is given in the following table:

TABLE I.—*On Tensile Strain.*

Approximate thickness of plates in inches.	Mean density of plates.	Mean breaking strain per sq. inch in tons.	Mean elongation per unit of length.	Mean work *u*, for unity of length section done in causing rupture, in ft. lb.
$1\frac{1}{2}$	7.7471	24.453	.1769	4,844
2	7.7684	25.169	.3703	7,620
$2\frac{1}{2}$	7.7660	24.569	.2658	7,314
3	7.7666	25.031	.2689	7,538

The second series of experiments was upon compression, yielding the following results:

TABLE II.—*On Compression.*

Approximate thickness of plate in inches.	Mean ultimate pressure per sq. inch in tons.	Mean ultimate compression per unit of length.
$1\frac{1}{2}$	90.967	.513
2	90.967	.518
$2\frac{1}{2}$	90.967	.510
3	90.967	.511

The third and most important series of experiments was that on punching and shearing. It was supposed that the resistance of armor plates to the impact of shot was analogous to that produced by statical pressure. Under this supposition it was thought desirable to institute a series of experiments to ascertain to what extent the law was applicable to the resistance of iron plates by punching, in order to apply it to the more important experiments on impact. These experiments—made with a flat-ended punch—fully established the formula that the resistance of armor plates to a force tending to perforate them, varies as the diameter of the punch, multiplied by the thickness of the plate or the depth of penetration.

Another series of experiments with a round-ended punch was instituted by the Iron-plate Committee for the purpose of comparing the resistance of armor plates to flat-ended and round-ended projectiles, and tables were given to show that the statical resistance to punching was about the same whether the punch was round-ended or flat-ended. The following is the general table of comparison:

Description of Gun.	Weight of shot in lb.	Charge of powder in lb.	Velocity in feet per second.	Semi-diameter of shot.	Maximum thickness of perforation. By experiment.	Maximum thickness of perforation. By formula.	Error of formula.
Armstrong 6-pr......	6.25	0.75	1,141	1.22	1.286	1.406	$+\frac{1}{11}$
Armstrong 12-pr.....	11.56	1.50	1,155	1.46	1.803	1.769	$-\frac{1}{53}$
Armstrong 25-pr.....	24.81	3.13	1,169	1.84	2.350	2.337	$-\frac{1}{180}$
Armstrong 40-pr.....	40.00	5.00	1,166	2.34	2.820	2.663	$-\frac{1}{18}$
Armstrong 100-pr....	110.00	14.00	1,175	3.45	....	3.613	....
Smooth-bore 68-pr...	66.25	16.00	1,557	3.96	....	3.470	....

Mr. Scott Russell said, in regard to spherical shot, it was a well known law that if they took a plate of the semi-diameter of the spherical shot, it was just equal to the resistance of the shot. If he took the experimental column in Fig. 5, and took the semi-diameter of the shot as given in the fourth column, he saw, on the whole, no great deviation from this law; it seemed to be the simplest possible expression of it. 1.22 was the semi-diameter of the shot, and 1.28 was the maximum thickness of perforation. If he took the next figure, 1.46, then the other, 1.80 was greater; if he took the next, 1.84, then 2.35 was greater; and 2.34 was smaller, and 2.8 was again greater. These were elongated shot. As far as these experiments went, it would appear simply thus, that for the smaller diameter they might take the semi-diameter of the shot as the thickness of the plate; but as the diameter became larger it required a somewhat thicker plate to resist it. That was a summary of the conclusions given in the paper.

Mr. E. J. Reed said this paper had a value of a peculiar kind, because it placed before the Institution the experimental results obtained by Mr. Fairbairn in connection with the investigations of the Iron-plate Committee, which investigations had up to that time been a sealed book to the Institution and to the public. Several points required explanation. Among others the following: He did not quite understand what was meant by saying that the indentation was .37 with a round-ended punch, and .1 with a flat-ended. He presumed the undulation was measured to the innermost point of the punch, and if so, the comparison between the perforation with the flat-ended and round-ended punch would be very different to what the figures represent. Again, he could not persuade himself that the first formula written down was strictly accurate; that, in point of fact, the pressure was entirely proportionate to either the thickness of the plate or the indentation; because if they took the amount of force expended in punching a plate, there would be a very great variation in the amount of force exerted upon that punch during its passage through the plate. He thought there would be a great diminution of resistance per element of perforation in proportion as they approached the inside of the plate; in other words, when they got nearly through they finished the work much more easily than when they commenced it, and the formula that P raised twice r^2, left that quite out of consideration.

Mr. Bramwell said he gathered from the paper that the experiments in punching plates showed the resistance to be directly as the diameter multiplied into the thickness of the plate. The formula on which they agreed put the value of a plate to increase as the square of the thickness. If that were so, it would seem the resistance of the plate to impact was very considerably different in its law to the resistance of the plate to punching. With regard to the round-ended punch, it was stated in the reading of the paper that the work done to perforate a plate by the round-ended punch was greater than to perforate it by the flat-ended punch. In perforating armor plates by shot when there was the same amount of work residing in the shot, the shot with pointed ends did its work with more facility than the flat-ended shot; so that there did seem to be a very considerable contradiction between the different statements in the paper.

The New Turret Ship "Captain."—The armor-plated twin-screw turret ship Captain, built by Messrs. Laird Brothers, of Birkenhead, from the designs of Captain Coles, as the representative ship of his turret system, was recently launched with her engines on board and completely fitted. There are two separate pairs of double trunk engines, each pair driving a separate screw propeller 17 ft. in diameter. The collective force of the engines is 900 horse-power, nominal. The general construction of the hull of the Captain is similar to that of the large armor-clad ships built for her Majesty's navy. The turrets, two in number, and each carrying two 600-pounder 25 ton guns, project through circular openings in the upper deck. The part exposed to shot is covered with armor plates 10 in. thick about the ports, and for one-third the circumference, and with plates 9 in. thick for the remainder, while the lower part and all the gearing is protected by 8 in. armor on the side of the hull. The height of the center of metal of the guns is 12 ft. above the water line, which will admit of their being fought at sea in very heavy weather. The turrets are each 29 ft. external and 22 ft. 6 in. internal diameter. The low part below the armor sheaf is constructed in a cellular form, large openings being left for entrance and for passing in ammunition; these openings serve also to ventilate and light the lower decks. The turrets are supported by a strong girder on the lower deck, and revolve on a series of cast iron rollers, being kept in position by a solid wrought iron spindle securely fixed in the deck and carried down to the orlop deck; they are fitted with a complete system of hand-turning gear in addition to the steam gear. This steam gear is worked by a separate pair of engines for each turret placed on the orlop deck below the turret, where they are thoroughly protected from any chance of injury. The gear for starting these engines is so arranged that it may be worked either on the lower deck outside the turret, or by a system of rods led up through the central spindle to the sighting platform by the captain of the turret himself, who can thus take aim and direct the guns in the turret.—*The Engineer*.

Butchers' Steel Frogs.—The last report of the chief engineer of the Reading Railroad says: "The result of our experience with the Wm. Butcher cast steel reversible frogs has been very satisfactory. Of 73 put down, only one has been removed, on account of defects at one end, and none have been turned."

Another Proposed Ship Canal.—The Greek correspondent of the "London Times" writes: "The project of cutting a canal through the Isthmus of Corinth has been again discussed at Athens, and some people here think that circumstances render the execution of the enterprise perfectly practicable and ultimately useful, even should it not be immediately profitable. In a few months the work of M. de Lesseps at the canal of Suez will be so far completed that a number of powerful machines, admirably suited for work at the Isthmus of Corinth, may be obtained at a comparatively small cost. Skilled workmen will also be ready for employment, whose labor could be obtained at an expenditure trifling in comparison with what Greece would be called upon to pay under any other circumstances. No such favorable opportunity of constructing a canal through the Isthmus of Corinth is ever likely to recur. A glance at the map of the Mediterranean shows how important such a canal would be for the trade of all the ports of France, Italy and Austria with Smyrna, Constantinople and the Black Sea. The ports at both ends of the canal would not require any very great expenditure, and the canal, if made, could be kept open at very little cost. Its length would be three miles and three-quarters, but there is an elevated plain of limestone through which it must be carried that rises to an elevation of 250 ft. for a length of more than a mile. It is calculated that to construct a canal 150 ft. broad and 40 ft. deep would require the excavation of about 12,000,000 cubic yards of rock and clay. Whether the work would be profitable or not to a commercial company, there can be no doubt that it would be more useful to the Greek nation, and would not cost more money than a fleet of iron clads to drive the Ottoman fleet out of the Archipelago, for which the Hellenes are raising subscriptions."

EFFECTS OF COLD UPON IRON.

From "Engineering."

All railway experience in those countries of which the climate presents extreme ranges of temperature has shown that rails break far oftener in winter than in summer. It has been suggested that the chief reason is that the road-bed, being frozen in winter, affords no elasticity to the sleepers, the spring of the ballast being supposed to afford a high protective power. A theory advanced by Mr. Colburn in 1863 has gained some acceptance, viz., that all iron is charged, to a greater or less extent, within its pores, with moisture. It is well known that water may be forced, almost in spray, through the walls of a hydraulic press cylinder under great pressure, and all iron is found to be more or less porous when the attempt is made to retain highly compressed air within vessels constructed of that material. It is a question how far the great expansion of zinc, tin and lead, indeed, of all the more fusible metals when heated, is due merely and solely to their low cohesive resistance, or to the expansion of interstitial moisture acting against a comparatively small resistance. If moisture be present, as there is every reason to believe it is in all iron, its freezing will fully account for the failure of iron rails in extremely cold weather.

In 1867 Mr. C. P. Sandberg, Swedish Government Inspector for railway materials for the railways of his native country, made a most important series of experiments upon the strength of rails at different temperatures—ranging from 10° to 84° Fahrenheit. To make sure that the question of the comparative rigidity of supports did not affect the results, he made his trials upon the planed surface of a granite rock, and upon which were placed two bearing blocks of granite, 4 ft. apart, upon which the trial rails were laid. Each rail was tested with a falling weight, a 9 cwt. iron ball raised progressively to heights varying from 5 ft. to 11 ft. The following most important table of results fully explains itself, and shows how brittle were the rails in extreme cold weather as compared with summer heat:

CLASS OF RAIL.	Progressive number of Blows.	Height of Fall of the Ball in Feet.	Permanent Deflections.	Broke	Temp'ture. Deg. Fahrenheit.

THE MARTINI-HENRY RIFLE.

Fig. 1.

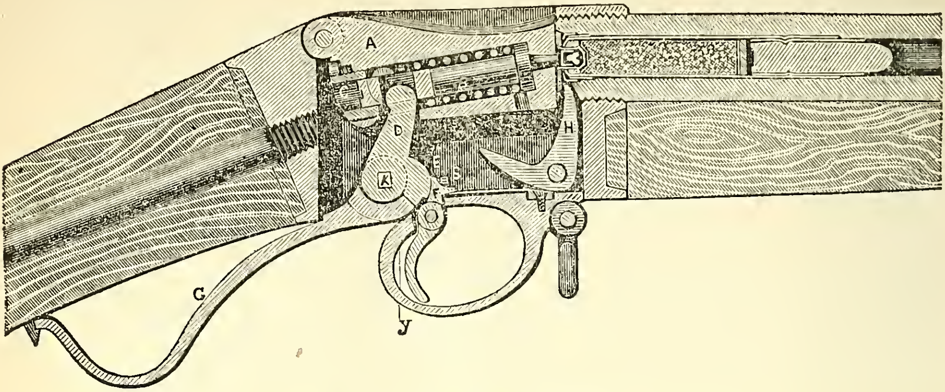

Fig. 2.

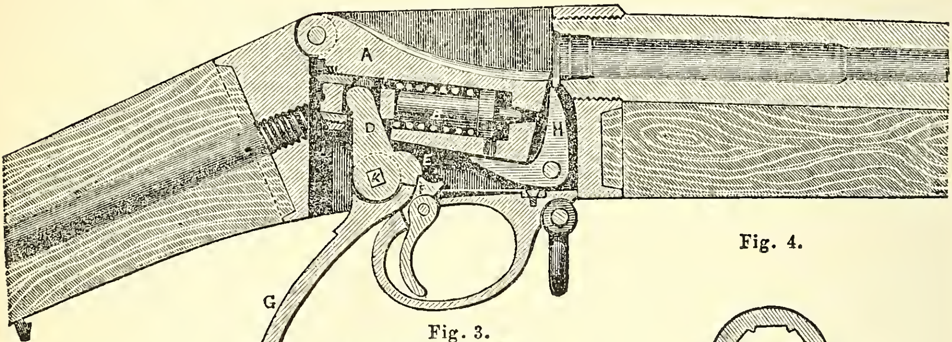

Fig. 3.

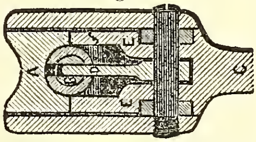

Fig. 4.

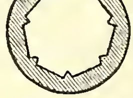

The question of the military arm of the future, which has been so largely discussed in England for some months, appears at last to be definitely settled by the adoption of a rifle bearing the above name. This weapon is the joint production of two inventors—Mr. Martini and Mr. Henry—the breech mechanism of the former and the rifling of the latter having been adopted by the Government. The progressive steps which have led to the final selection of this arm have been previously referred to. Nine breech-loaders were selected from more than a hundred which competed, and the final arm was selected from these. The arm has yet to be tested in practical use by the troops, a limited number of which will be first supplied with the new rifle. But we have no reason to apprehend that this trial will not lead to its final and general adoption in the English army; indeed, judging from the severe tests it has undergone at the hands of the Small Arms Committee, we should say there was no chance of failure on any point.

The breech mechanism, as adopted, we illustrate in our engraving, figs. 1 and 2, from which it will be seen that it is extremely simple in construction. Fig. 1 shows the breech closed with the striker forward, and fig 2, the breech open ready for loading. The breech block A works on a pin, and contains the striker B, surrounded with its main spring. This striker is confined in its chamber by the hollow screw C. The bottom of the breech block is slotted to allow the end of the tumbler D to engage with the striker. The tumbler is mounted on the axis K, which is squared at the point of contact with the tumbler, so that as the tumbler is raised or depressed the axis moves with it and so alters the position of an indicator outside the lock. The hand lever G, in its downward movement, serves to open the breech and draw back the striker. The tumbler moving with the lever engages itself on the nose F of the trigger. A further continued downward movement of the lever G acts against the inner face of the hollow screw C, and causes the breech block A to lower itself on its pin as a center. The upper part of the lever G is forked, and embraces the tumbler as shown at E E, fig. 3. As the lever is pressed down, the breech block is opened, and, as it moves, the tumbler is forced back, drawing back the striker, and compressing the main spring at the same time, till the nose F of the trigger engages with the tumbler rest. The object of the tumbler rest is to relieve the trigger from the whole weight of the tumbler and main spring. As the trigger is pressed, its first movement relieves the tumbler from its rest. The whole weight of the spring is now on the trigger, and a further pressure releases it. The working of the extractor is easily understood from a glance at the engraving; but at the same time it will be well to remark that the lower arm of the extractor H is so shaped that the first impact of the breech block with it serves to loosen the cartridge case in the chamber; then, as it further descends, the motion of the extractor is more rapid, and the case is ejected clear of the gun. Fig. 3 is a transverse section of the breech block mechanism through the plane $x\ y$, fig. 1.

In the early patterns of the Martini system an indicating pin was provided at the back of the breech block and in the upper part of the stock, which projected when the arm was cocked. This indicator was worked by the head of the striker, and as it was found to get out of order, another and more simple indicator was substituted. As mentioned above, this last improvement is fixed on the end of the tumbler axis, and therefore shows exactly the position of the tumbler. In order to obviate any danger that might arise through carrying the arm loaded and cocked, the committee added a safety bolt S, which engages with the trigger, and prevents it being moved. Other minor improvements have been made, such as lightening the cleaning rod, and modifying the shape and position of the sight.

The cartridge for this rifle is the invention of Mr. Henry, and, as it will be contained in a central-fire Boxer case, it is called the Boxer-Henry cartridge. It is 450 gauge, the bullet weighing 480 grains, and is composed of lead hardened with tin. A paper wrapper is placed round the bullet, the edges being returned into a slight cavity at its base. Pure beeswax is used for lubrication, and is placed between three discs made from jute cardboard. The charge consists of eighty-five grains of powder. This cartridge is shown in section in the barrel of the rifle at fig. 1.

Turning from the breech mechanism and the cartridge to the barrel of the new arm, we may observe that it is 35 in. in length, and is rifled upon Mr. Henry's principle, shown in section in fig 4. This is known as the polygonal system, and is seven-sided. Down each angle formed by the intersection of the planes of the polygon is a raised rib, which is tangential to the same imaginary circle as that to which the plane sides of the bore are tangential. This form of rifling leaves the bore more cylindrical than any other, except perhaps the Armstrong many-grooved system. In it what Mr. Henry terms a re-entering angle is formed, thus affording to the bullet a bearing at fourteen points instead of seven. The pitch of the rifling is one turn in 22 in., the caliber being 460 of an inch. The Henry barrel has proved itself singularly free from fouling, and the excellency of the rifling has fully maintained itself to the last. A rifle on this principle was fired 3,000 times without its accuracy being in the least degree impaired. With the cartridge above described, the Woolwich practice in the latest trials has habitually given the unparalleled result of lodging the bullets in a square of about $2\frac{1}{8}$ ft. at a range of 1,200 yards.—*Mechanics' Magazine.*

NEW RAILWAY BRIDGES—THE KEYSTONE BRIDGE CO.—The Newport and Cincinnati bridge, now in charge of Mr. Linville, President of the Keystone Bridge Co., has the greatest span of permanent railway bridge truss on this continent, viz., 420 ft. The same engineer is erecting an iron bridge over the Mississippi. at Keokuk, consisting of eight spans of 164 ft. 6 in., two spans of 250 ft., and a pivot span of 370 ft. This bridge is designed for railway and road way traffic, the width in the clear being 20 ft. It is proportioned to carry a rolling load of 3,000 lb. per foot with 6 as a factor of safety.

The Keystone Bridge Co. are erecting one of their patent pivot spans of iron, 360 ft. in length, at Kansas City, the remainder of the bridge being of wood, with wrought iron lower chords, from the designs of O. Chanute, chief engineer. The spans vary from 140 to 250 ft. The same company is erecting a double track iron bridge for the New Jersey R. R. and Trans. Co., at Newark, with two permanent spans of 96 and 115 ft., and a pivot span of 217 ft.

The great wooden bridge over the Susquehanna, at Columbia (to replace the one destroyed after the battle of Gettysburg), consists of 26 spans of 200 ft. each, one span of 150 ft. and two iron spans of 100 ft. each. This was designed by Mr. Linville, and erected by the same builders—some 6,000 ft. in length in all—between May and December, 1868. Numerous smaller iron bridges are building by the same company for the Pennsylvania, Fort Wayne and Chicago, Northern Central and other roads. Most of the iron bridges on the Pennsylvania Railway, and those on the Connecting Railway at Philadelphia, were designed by Mr. Linville. Several of them are large works, such as the iron span of 262½ ft. over the Schuylkill.

EXPERIENCE IN DESIGN.

From "Engineering."

Engineers are frequently called upon to design structures, the proper proportions of which cannot possibly be determined by any process of mathematical investigation, no matter how refined or laborious. Under such conditions a careful consideration of similar works already executed is absolutely imperative. The successes attained and the defects evinced in many of the works of our predecessors afford evidence which it would be inexcusable to neglect. "*Scitum est periculum ex aliis facere, tibi quid ex usu siet*" is as sound a piece of advice now as it was 2,000 years ago, and to no one does it more forcibly address itself than to the young engineer. The mathematical training every student of engineering now undergoes is somewhat apt to give him an excess of confidence in the exactness of his own deductions, little less objectionable in its practical effect than the timid and slavish adherence to precedent evinced by the proverbial "practical" man. He is, by the same system of training, led to form a ridiculously low estimate of the extent to which the most approved practice of the present day is indebted to inductive processes. By far the larger proportion of the varied problems the civil engineer is called upon to entertain will be most readily and satisfactorily solved by deducing the required result from certain data previously arrived at by the process of induction. In one respect the science of engineering differs from most of the other exact sciences, inasmuch as it is seldom necessary to investigate any problem extensively by induction; the practically correct, and not the theoretically exact, solution is the requirement of the engineer, and it is, therefore, merely necessary for him to trace back sufficiently far to allow of that end being attained. Thus, an analysis of experiments on the transverse strength of beams indicated the existence of an element of strength dependant upon the form of cross section, and varying with the nature of the material; and in the same manner the resistance of long columns has been found in practice to be higher than theory indicated. In each of these instances it is only necessary for the engineer to ascertain enough of the laws governing the increased resistance to enable him to include that element in his calculations, and it is not necessary, although it may be interesting, to ascertain the first cause of the anomalies exhibited in many of the experiments.

The structures falling within the province of the civil engineer are generally so far analogous as to render the ordinary plan of procedure by deduction quite justifiable; but with the mechanical engineer it is otherwise. The conditions under which his works are placed are so involved, and they are so often liable to strains of literally indeterminate amount, that any attempt to generalize would be perfectly futile. Thus, given the resistance of a cylindrical bar of wrought iron to a bending, and also to a twisting stress, who could presume from such data to deduce the proper proportions and sections of the crank shaft of an inside cylinder locomotive? It would be necessary to eliminate the bending stress, and that alone would be made up of the several elements due to the reaction of the driving wheel springs on the roughest portions of the line, of lateral blows on the flanges of the wheels, of the steam pressure on the piston, and of the *vis viva* of the gear and the crank shaft itself. When we consider the *form* of the member which has to sustain these constantly varying stresses, in conjunction with torsional and other strains, it is very apparent that the necessary section and the most economic distribution of the material could only be arrived at by a strictly inductive process. Who, again, could attempt to compute the section of tyre desirable for the driving wheels of the same engine, and yet the practical identity of the proportions adopted by the different makers in this and in other countries, both for the tyre and the crank shaft, clearly prove that these apparently indeterminate problems have been solved by induction with as much exactness as the tensional strength of a two inch square bar may be arrived at by deduction from that of an inch square bar. These considerations should prove reassuring to the civil engineer when confronted with problems of more than average intricacy.

Complex formulæ are rarely resorted to by experienced practical men, the reason for which will probably be found in the fact that too great attention to minutia in the calculations is apt to make a man imagine that the chief portion of his work is accomplished when he has solved the problems relating to strains in the structure, and so induce him to overlook some apparently trifling practical detail, the neglect of which might, after all, be of sufficient moment to cause his work to be classified as a warning rather than as an example. No intelligent engineer, when designing a complicated structure, hesitates to throw over entirely his theoretical deductions, should the proportions thus determined appear unsatisfactory to the eye, because experience has taught him that, in nine cases out of ten, the discrepancy between the proportions deduced and those anticipated is due to the falseness of the hypothesis upon which the theoretical conclusions were based, and not to any error of judgment in that very trustworthy guide—the experienced eye.

We doubt whether that historical *faux pas*, the continuous fish-bellied rail, is justly credited to a member of our profession. We think the idea must have originated with some worthy mathematician, who fondly imagined that perfection was approached in exact proportion to the number of decimal places in his calculated ordinates. A purely practical man would, we feel sure, have instinctively rejected the pseudo-scientific form, although he may not have been able to point out the error in the hypothesis to which the vicious result was due.

Many other instances might be cited where purely theoretical deductions are equally at fault; as a case in point we may refer briefly to the bracing of a bow-string bridge. Numerous and elaborate formulæ are to be found in French and German text books, professing to define the exact value of the maximum strain occurring upon each tie and strut under the passage of a moving load, but unfortunately in nearly every instance these formulæ are based upon the hypothesis that the system is perfectly rigid, or, in other words, that the length of each member of the bridge will remain constant under every degree of strain. Now we know that some deflection must necessarily follow the application of each successive increment of load, however small, and we know also that such deflection could not take place unless the length of every member in the bridge differed, plus or minus, from its original amount. This of course is due to the elasticity of the material, and the complicating conditions thus introduced are so embarrassing, varying as they do with the relative sectional areas of arched rib, tie, and bracing at each portion of the length, that it would be an almost endless task to deduce the exact mathematical value of the maximum strain occurring upon each member of a bowstring bridge under a rolling load of known intensity. No intelligent engineer wastes his time in the investigation of such problems, because he knows that after all the result of his labor would be of no practical value.

It would have been assumed that the whole of the metal in the bridge was in a state of molecular equilibrium in the absence of any external stress, or else that certain members were subjected to initial strains of known intensity. To enable the first hypothesis to obtain, the bars and plates would all have to be of precisely the required length, and accurately fitting, whereas in practice we know that in the process of riveting one bar would be drawn up tight, whilst probably the adjacent one would be quite slack, or even present a permanent lateral curvature. Or, again, in putting the girder together it may have been necessary to "draw out" one of the ties to make it fit into its place, and, probably enough, it would have been riveted up when quite hot; but this apparently trifling, and certainly unavoidable, practical contingency would be sufficient in many instances to augment the laboriously deduced theoretical strain as much as 50 per cent. If cotters were introduced, either for the purpose of securing uniform or initial strain, the value of the result would be entirely dependent upon the intelligence of the men entrusted with the cottering up; and with the best arrangements the degree of uncertainty would be little less than the previous instance. It is quite possible to obtain, by mere inspection, the strains on the several members of a bowstring bridge within 25 per cent. of the amount which would be given by the most elaborate mathematical analysis; consequently, remembering that it is impossible to make sure in practice of approximating even within 50 per cent. to the exactly deduced result, we think the adoption of an elaborate method of calculation for the minor members of a bowstring bridge, and for similar reasons for the strains upon an almost infinite variety of other structures also, only serves to prove that the conditions of the problems are imperfectly appreciated by those attempting to solve them.

HORSE POWER.

From a paper read by J. S. Holland, C. E., R. N., Assoc. I. N. A., before the Institution of Naval Architects.

The principal use of the steam engine at its first introduction was to pump water out of mines; it easily followed that the new engine should be compared with horses then in use for pumping, hence the term horse power of an engine. Watt would undertake to make an engine do the work of so many horses. Being generous he considered that a horse could raise 33,000 lb. one foot high in a minute; he fixed upon that for his horse power. And although he knew that the mean pressure per square inch of his piston would be more than 7 lb., he, to avoid all cavil with his customers, generously fixed upon 7 lb. as one of his factors in calculating horse power.

Knowing that a long stroke engine could work easier at a high velocity than a short stroke, he formed for himself a table of velocities of pistons for various strokes, and, at the time, it was formed on sound principles. So far as marine engines are concerned that table has long been obsolete. The 7 lb. are still retained, but the engineer is allowed to fix his own velocity of piston in his tender on negotiation with the shipowner. This brings me to the subject of this paper. It is the false statement in the tender that I object to. Let us see what takes place at the beginning of a pair of marine engines. Assume that after every consideration has been given to the subject, a power of 6,000 horses will have to be developed. He calculates what he can do in the way of pressure on the piston, he then fixes his velocity, which being determined, the diameter of cylinder follows as a matter of course; he then determines the firegrate and heating surface of his boiler, and the work is done. All this time he has never thought of such a thing as nominal horse power. Yet there is something else to be done. If the shipowner likes to have his engines working up to six times their nominal horse power, clearly there is nothing left for the engineer but to christen his engines 1,000 nominal horse power, and if the shipowner likes to be cheated a little more you have only to christen the engines 600 nominal horse power, and you have ten times the nominal horse power. You may accommodate the shipowner to any extent, but you must not tamper with the power to be indicated.

A case is now before me. An engineer stated in his tender that the revolutions would be 44 per minute, in working they went more than 88 per minute, the pressure was about 22 lb. Now, the pressure being over three times the nominal and the velocity twice, he counted over six times the nominal horse power, and was patted on the back accordingly. If we are to have nominal horse power retained, we must stick to the old 7 lb. and reckon fairly and honestly the velocity expected. Then, if the engineer has made no blunder the engines will move very near the expected velocity, and if they do and give out three times the nominal power, we know that there was a pressure of about 21 lb. In the case I have named the engineer knew well that his engines would go 88 revolutions; he made his screw and his boilers to suit the number of revolutions. The question may be asked, why did he give forty-four revolutions? The answer is plain enough: there is a demand in the market for engines that, under one pretence or another, can be said to have contained their nominal horse power so many times in their indicated power, and where there is a demand there will always be a supply. It is against this practice I enter my protest.

If shipowners and shipbuilders knew the

contents of this paper, we would have little more chuckling of six, seven, or ten times the nominal power. If nominal horse power is to be retained let the pressure be still 7 lb.; let the engineer state fairly his expected velocity, and let credit be given to him for getting as much pressure into his cylinder as he can from a given boiler pressure, and for coming near to his predicted velocity.

As for nominal high pressure there is no such thing. As it would be better to keep nominal power and indicated power as wide apart as possible, I would propose that what is very nearly an average, 10 lb., should be taken as the mean pressure. Nominal horse power has been called a commercial measure. If it ever was, it is no such thing now. Engineers know nothing about it; they are required to produce so much effective power, and they set about to do it. It will weigh so much, cost so much, and they make up their accounts.

I propose to abolish the term nominal horse power altogether; it is not only useless, but pernicious. Shipbuilders are not called on to make vessels carry six or ten times their nominal tonnage, and, I ask, why should not engineers be allowed to be put on an equality with them, and have the privilege of calling a spade a spade?

RAILWAY FERRIES.

From a paper read before the Institution of Naval Architects, by J. Scott Russell, Esq., F. R. S.

One of the great unsolved problems of modern engineering is to complete the wanting links of European railway communication by joining Dover to Calais. That is the missing link in the unity of European civilization. It is also the missing link in material commerce. Railway trains laden with the wealth of nations run smoothly down to the banks of the sea on either side, and are there abruptly stopped — rudely broken up—their contents strewed over the quays—craned and laden into ships—uncraned and unladen on the other side—again stowed on wagons before they can continue their second railway journey, and thus, on a short sea gap of some 20 miles, endure more delay, undergo more wear and tear, and cost more money than on a hundred miles of railway.

That which is merely wasteful and costly in the transport of material merchandise, becomes degrading and barbarous when applied to human beings. The transport of civilized human beings between the kingdom of Great Britain and the empire of France is disgraceful to two civilized nations. The traffic of human beings between Calais and Dover frequently exemplifies some of the worst features which have been pictured of the African slave trade. We are told of 150 negroes huddled under the decks of a ship where they have not even room to lie down—where the air is pestiferous—where human beings are willing almost to throw themselves overboard to escape a state of existence that has become intolerable. What we have *seen* between Calais and Dover is, a hundred, or a couple of hundred, civilized human beings, citizens of refined communities, systematically huddled under decks, where there was neither room for comfort, rest, ventilation, cleanliness, nor health. We have seen fifty delicate, refined women crammed into a cell where they had just room to sit jammed together on the floor. Just before starting a benevolent stewardess placed on the knees of each a convenient basin, and, a few minutes later, an anxious husband, descending from the wet deck to inquire after the welfare of his delicate wife, found it hard to endure the close, confined atmosphere to which, nevertheless, he was obliged to abandon her. Which of us has not passed over this purgatory without meeting some intelligent foreigner who swore that never again would he pay such a penalty for visiting England, and never would he counsel man or woman of his acquaintance to undergo the miseries and humiliation of this miserable passage over the sea channel!

In truth, this great international communication between Europe and England is a degradation to all who endure it—a disgrace to three great railway companies—a blot on the administration of a great Emperor; and when we think ourselves the most practical nation in the world, we are really perpetuating a great arterial system of communication which is barbarous and thoroughly unpractical.

It is well, therefore, to consider, in this meeting of naval architects and marine engineers, whether this state of international communication arises from any impossibility or impracticability standing in the way of expeditious, comfortable, and economical means of railway transport over the sea, or whether the causes are moral, financial, or intellectual incapacity in those who have the duty and responsibility of providing this public highway.

First, therefore, I may state that it is not the fault of engineers and naval architects that the public does not now enjoy the advantage of a railway across the sea. More than three years ago an association of Englishmen was formed to carry railway trains across the sea between Calais and Dover. Of this association Mr. Fowler was the civil engineer and I was the naval architect. All the measures which a private association of individuals could take for giving to our nation and other nations a civilized communication were taken. Neither pains nor time were spared, and large sums of money were spent in making every preparation for giving the public this benefit. Unluckily we had to deal with an apathetic public, and with railway companies already in possession of the ground, with rival interests and disordered finances. The same bad political economy which has abandoned the public works of England to private speculation rendered it impossible for this work to be then achieved, except through the co-operation of railways in a state of war and dilapidation. But the technical work had been thoroughly done. The harbors on both sides had been surveyed, and the working plans completed by Mr. Fowler; the designs of the ships to carry the railway trains across the sea had been completed by myself, and there, on the table, is the model on which they were to be built. The Act of Parliament was applied for, the money for all the expenses was found, and it was not the blame of engineer and naval architect that the thing was not then begun, and now done; there were no engineering difficulties not then solved.

I am now to have the pleasure of bringing before you, not the proposed plan for bridging the sea between Calais and Dover, but a similar undertaking which has been executed, and which is now in successful operation across a sea on a smaller scale. The channel between Dover and Calais is 20 miles, and the sea of Bodan is at most 10 miles to 12 miles broad. There is the same difficulty of shallow water and narrow harbor entrance as at Calais, but extreme low water is rather shallower, and the harbor entrance narrower than at Calais. Of course there is no Atlantic wave, and no ocean ground swells, and therefore no low, long swelling *bas vis*, and, consequently, never in the worst storm the great motion of our seas. But there is, to an even greater extent than on the Channel, the sharp, short, breaking wave, which is both more dangerous and inconvenient than the long low swell; there is the terrific hurricane that swells down from the Alps, and which is probably not inferior in strength to a heavy Atlantic gale, and there are quite as many days in the year when no steamer can venture across the sea of Bodan, as when no steamer can cross the Channel. I think, therefore, the sea of Bodan is a fair scale on which to test a plan for conveying trains across the sea. Take it as half the distance with waves half the size, wind half the strength, harbor entrances half the width, and a steamer half the length, and it will probably be considered as fair an experiment as can be tried.

The peculiar circumstances of this case are such as to present many difficulties, which need not be presented either at Dover or Calais. At Dover there is plenty of water; at Calais there is means of getting as much water as can be wanted, and an Emperor who has cut his way through the Isthmus of Suez can easily dredge a little sand out of the entrance to Calais; but on both sides of the sea of Bodan the water is shallow, while in the middle it is deeper than the Channel.

The entrance to the harbors in this lake is less than 100 ft. of clear width, and one of them is so narrow inside as to be only two ships' lengths. The ports, therefore, present greater difficulties than Dover and Calais; but there are no tides; that is to say, no daily rise and fall of the water; nevertheless there are periods of rise and fall of 10 ft., or, again, about half the ordinary ranges between Calais and Dover.

The Sea of Bodan, or Bodan Sea, or Lake of Constance, is an inland fresh water lake, 60 miles long and 10 to 12 miles wide. It separates Switzerland from Austria, Bavaria, Würtemberg, and North Germany, all of which have railway communication with Switzerland, and through Switzerland with central and southern France, which is cut off short and stops abruptly on the shores of this lake, and this natural barrier of the lake is prolonged right down into Italy by the impassable Alps. The railway trains which last year fed France from the cornfields of Hungary, carried a continual stream of grain across Switzerland into France; but on the edge of this lake all this traffic was stopped—all the grain that might have passed right through in a wagon, from Pesth to Lyons, had to be unladen from one set of wagons at Lindau, in Bavaria, or Friedrichshafen, in Würtemberg, shipped into steamers or barges, unshipped on the other side, and reladen into a new set of wagons. The cost and delay of this system, the accumulation of empty or laden wagons on both sides, the army of men for moving the sacks from ship to land, and from land to wagon, the accumulation of sacks on quays and under sheds, caused a hindrance, an inconvenience, and an expense, to avoid which many preferred to send their wares a long way round.

The impediment for passengers across the Bodan Sea was similar to that between Calais and Dover, although the accommodation for passengers on both sides presents those facilities which have only quite recently been introduced in our harbors, for on both sides of the lake the Swiss and German trains convey the passengers alongside the quay at which the steamers lie, and the passengers present to the companies this advantage over goods, that they are able to tranship themselves at their own inconvenience only.

Under these circumstances I was asked by M. Boller, an eminent Swiss engineer, and M. Schweizer, an able Swiss railway director, whether I would undertake to design a communication across the Sea of Bodan by which railway trains and locomotive engines should pass continually over the sea without interruption, and without change of carriage, so that a bale of goods, or a passenger, placed in a carriage in Switzerland, or in Germany, should pass right through from Vienna, Munich, Stuttgardt, Dresden, or Berlin to Zurich, Lucerne, Bale, Geneva, Lyons, Marseilles, or Paris, or contrarywise to it. It was also a condition that I should, if possible, employ no steam engines, machinery, or power of any kind in the transfer, except the ordinary locomotive engines employed in dragging the train; in short, I was asked to make an international communication across this sea as continuous and unbroken as between two stations on land.

This I have now accomplished, and after frequent preliminary trials it is now doing its daily work of railway communication. It takes trains of 14 to 16 laden wagons at one time. The wagons weigh 70 to 80 tons, their contents 150 tons; they make the passage from harbor to harbor in from forty to fifty-five minutes, the difference being the index of the severity of the weather. The cost of the goods per ton per mile, varying with the quantity on board, is from three farthings to five farthings, including interest on capital, depreciations, and repairs. A locomotive engine on one side places the train on board; a locomotive engine on the other side takes it out. No peculiarity is required in the engine nor in the mode of working it. No peculiarity is required in the wagons, carriages, their brakes, or their construction. The embarkation of a complete train occupies five minutes, its debarkation five minutes. All the practical difficulties which were anticipated and feared have disappeared with the actual facts, and that which was pronounced as so many new or impossible enterprises is now acknowledged to be "kinderspile," or child's play. Indeed, now that it is done, the thing seems so obvious and simple that on returning home across the English Channel by the Straits of Dover, I was totally at a loss to conceive the reasons which could induce the intelligent English people and the great French nation to continue to endure the evils of this barbarous passage across the sea, while little Switzerland and little Würtemberg had provided for a less sea a convenient and unbroken highway.

I will now shortly describe the means by which this railway passage over Lake Constance is accomplished. The Swiss railway which passes from Zurich to Romanshorn, on the Bodensee, is called the Nord-oest-bahn. On the opposite side the German railway terminates in Friedrichshafen, and is one of the royal Würtemberg lines, constructed and worked by the State. Both harbors are so shallow that 6 ft. is the maximum draught of water given for the ship. To carry the prescribed load of 14 to 16 carriages, two lines of railway are necessary on the ship throughout the length of 220 ft. For this purpose alone 22 ft. of breadth are necessary, and as engines and boilers have to be placed on both sides of the railway, the ship has a breadth of nearly 40 ft. without the paddle-wheels, which being each some 10 ft. wide, the boat over all has a width of 60 ft.

The vessel itself, standing in its place in the harbor, appears to form a railway station, the land lines of railway being continued straight on throughout the length of the ship. The vessel has two decks, one below the railway train and the other above it. The upper deck forms a great part of the strength of the ship; double sides of iron plate connect the upper with the lower deck, and convert the whole body of the ship into an iron girder 25 ft. deep at the centre, a construction which gives great strength to the body. The upper deck is the working deck of the vessel, from which the captain commands the engines, and where there are also two steering wheels for the pilots. There is a rudder at each end, so as to save the trouble of turning in the narrow harbors. Each paddle-wheel can be worked independently of the other, and each has two steam engines, so as to work readily and quickly, the four steam engines making up 200 horse power to propel a ship of 1,600 tons. The upper deck does not extend quite to the ends of the boat, so that passengers in carriages occupying the ends are left free to enjoy the Alpine scenery without leaving their carriages, and those who prefer a change, find on the elevated deck a fine weather promenade.

The difficulty of uniting this ship to the railways on either side, so that the trains can run on and run off without the aid of any steam engines or machinery beyond their own locomotives, is overcome by means of a bridge in the air, suspended by heavy weights, capable of adjustment to the rise and fall of the water; and there is in the vessel a further provision to lower or raise her own extremities through a range of five or six feet, so as to diminish the inconveniences of the varying water level. There are, moreover, in the ship self-moving capstans, by which the engines can perform any exceptional manipulation that may be required either for the railway trains or the ship itself.

It is by this combination of all these contrivances that a navigation, which would otherwise have been impossible, has been rendered easy and certain. These rudders and the two independent pairs of engines are an invaluable security against accidents, for one rudder being damaged, or its steering gear broken, an independent steering apparatus is ready for immediate use. In case of accident to either engine, or either paddle-wheel, the other wheel with its pair of engines is ready without a moment's delay to continue the voyage, and this experience has already been obtained, and the ship has performed a trip in less than an hour with one wheel and its engines; 15 deg. of the rudder were found sufficient to steer a straight course, leaving an available steerage of 30 deg. each way to direct the ship, and her captain found no difficulty in entering the harbor and placing the ship.

There is another result of the arrangement of engines adopted in this case, which has proved of the highest practical value. Each wheel has a pair of oscillating engines similar to those of the Great Eastern. I designed the paddle-wheel engines of the Great Eastern so as to be able, like these, to work each paddle-wheel independently of the other, and the result has proved, in this instance, to be of great importance. When large vessels come into shallow water they are well known to steer wild, and their rudders cease to control their movements; by the prompt action of the independent paddle-wheels, which can be made to revolve either in opposite directions, or in the same direction, one fast or one slow, or one altogether stopped, there is no evolution performable by a rudder which cannot be quicker and more handily done by the wheels alone, and this paddle-wheel steerage in shallow water, and in the entrances of harbors, has this great advantage, that it can be performed without way on the ship, or with as little speed as you choose.

For this particular case steerage by wheels has been found of greater value, and I dwell on it because there are some difficulties in the way of its successful execution. The engines must be contrived, as those of the Great Eastern were, for prompt reversal; a code of signals must be contrived so that at the same moment the captain can give different or contrary orders to the engineers of opposite engines; not only so, but the code of orders, to be successful, must give more precise instructions to the engineer than are commonly given. The contrivance of this code and its use require superior intelligence in the captain and in the engineers; but the result has been found to be well worth the pains. The captain has a conning platform in the centre of the upper deck, and thence a speaking tube to each engine-room; each engine-room has also an index which shows the engineer of one what the other is doing. The captain has also two indices on deck which show him what each engine is doing, and so the captain and his two engineers are always at one, and thus a mistake is no sooner made than seen and remedied.

With a proper code of signals and the arrangement I have described, an intelligent sailor will readily see that he can do everything he wants; he can reverse the course of his ship in four, three, or two minutes, according as he uses both engines—one standing, or one reversed. When at rest, he can revolve on a pivot without moving; and when he wishes to run on a circular arc, he has only to order the right number of revolutions to be made with the outer wheel, and a smaller number to be made with the inner wheel, and the curve is described as accurately on the water as with a pair of compasses on a sheet of paper. To steer straight without a rudder is performed by each engineer watching the index of revolutions of the other engine, which is close to the handle governing his own, and with an occasional hint from the captain. After a a little experience this becomes quite easy.

As to the manœuvering of the trains and placing them on the ship, the arrangements are so simple that all difficulty has disappeared; and whereas it was supposed that sufficient experience might only be gained after serious accidents, the experience has been gained and the daily work proceeds without accident. No locomotive engine—not even an empty wagon—has been sent into the sea—events confidently expected. Carriages intended to cross the sea are left at the siding which leads to the ship. The locomotive engine which does the work of the station goes behind this train and pushes it on to the ship, one half on one side, and the other half by a second line on to the other side. The common brakes of the train and of the engine suffice for all the manipulation of the train, and there are special means in the ship herself to prevent the trains at sea from fetching way. In practice the locomotive engines do not cross with the trains, for the Germans prefer their engines and the Swiss theirs. Only carriages and wagons go right through, and instead of 30 tons of locomotive, 10 tons of carriage, and 20 tons of goods more profitably occupy its place.

I trust this verbal description, together with the official plans from which the ship was built, will give a sufficient idea of the manner in which the crossing the Straits of Dover may be safely undertaken and successfully executed; some of the difficulties are greater, and some are less. There is deep water at Dover, and Calais can be easily deepened. The boats must be twice as long, and can be made twice as fast. Suspended bridges can easily be thrown from the land to the ship, as I have done; but with the changes necessary to the greater and continued variations of the tidal waters. In these larger and faster ships there can be room, comfort and ventilation, and, if built with the proper kind of stability, sea-sickness will nearly disappear. The comfort of taking your bed-carriage in London, and not having to leave it till you awaken in Paris, need not be enforced, and the economy and expedition which must arise from sending goods right through to their destination without change of carriage or wagon is thoroughly appreciated by all merchants and shippers. That the trade of Europe with England would enormously increase who can doubt. and the mails of India would reach Brindisi or Marseilles in the same carriages in which they would be stowed by the post-office officials of St. Martin's-le-Grand. The question as it stands is, therefore, whether patient Englishmen will remain quietly content that the communications of their railway traffic between England and all Europe should continue in their present condition of barbarism.

In conclusion, I must say that it is not me the English people have to thank for having made this experiment for them, to show them the practical way of continuing railway traffic over a wide sea on a large scale. I have already said that the problem was proposed to me by M. Schweizer and M. Koller, and not by me to them. The plan was first practically taken up by the President Escher and the Direction of the Nordostbahn, a railway managed and made by the Swiss, completed and set to work on less than its estimated capital, and in consequence of the wisdom, economy and purity of its management, now paying its shareholders a steady eight per cent. The proposal on their representation was willingly accepted by the Government of the small kingdom of Würtemberg, which has conferred on its people, by economical state management, a complete network of railways, at very small cost. These two bodies undertook to carry through this improved communication for their mutual benefit, and its management and government is now incorporated with that of the railways. Having previously built an iron ship, which has for twenty years done satisfactory duty on the same lake, I was asked to prepare the plans of a ship which should fulfil all the conditions of speed, safety, and manageability, which the circumstances required, and also of the works on land necessary to communicate with the ship. These plans of the ship, when prepared, were sent for public tender to several of the best firms in England, Scotland, France, Germany, and Switzerland, and it was intimated to them that if they chose to send in a design of any ship better, safer, or more economical, on a plan of their own, such a plan should have a preference over my own. The result was the acceptance of a tender by Messrs. Escher, Wyss & Co., of Zurich—a firm which, in the third generation, enjoys a high reputation for having covered the lakes of Switzerland with excellent steamships. They ordered the iron for the ship from the Creusot Ironworks in France, the pumps from Berlin, the capstans, anchors, and cables from England, and their performance of their contract has been accepted as satisfactory. The works on the land at Romanshorn were executed under the direction of M. Seits, the resident engineer of the Nordostbahn, and those at Friedrichshafen under the direction of chief engineers and architects Brockman, Binden and Grund.

THE FISH-JOINT.—It is generally known that the original fish-joint, as shown in figs. 1 and 4, was invented by Mr. W. Bridges Adams, of London, and patented by Adams and Richardson. It is not generally known that this excellent device, as at present used (figs. 2 and 3), was developed by Mr. Peter Ashcroft, engineer of the South-Eastern Railway. Mr. Ashcroft's

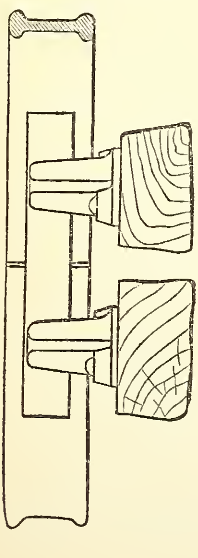

Fig. 1.

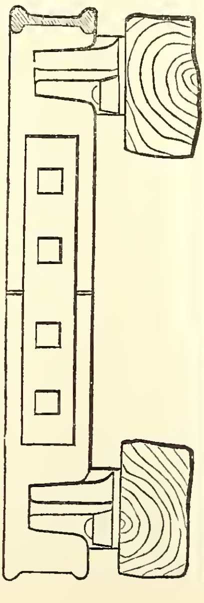

Fig. 2.

Fig. 3.

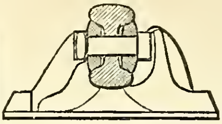

Fig. 4.

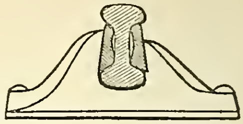

claims are thus set forth in a recent letter of his to Mr. R. Rice Williams, and published in "The Engineer":

South-Eastern Railway, Engineer's Office, March 10th, 1869.

My Dear Sir: In reply to your inquiries respecting the origin of the fish-joint used on railways, I beg to say that Mr. W. B. Adams properly describes the title of the patent as about the period referred to, viz., 1849–50. I was then and previously superintendent of the way and works of the then Eastern Counties Railway. When the fish-plate or wedges (see tracing) were first brought to my notice, I practically saw that a better form of suspended joint could be made by substituting bolts for the wedges; and at that time I had a foreman joiner of the name of Franklin (who now resides at Bishop Stortford), to whom I gave instructions to make templates for cast iron fish-plates. These were put down on the line between London and Stratford. They, however, did not answer, inasmuch as, from the unfitness of cast iron, they broke.

They were, however ordered by the Eastern Counties, and paid for by that company. The quantity was very small, that company having, up to the present time, the privilege of using them without any royalty whatever.

Immediately afterwards other patterns were made for joint-plates in wrought iron, and a large quantity were ordered; and, subsequent to my leaving that company's service, the majority of the company's lines were laid with them.

The old rails were punched for bolt-holes by a machine procured from Parr, Curtis & Co., of Manchester, which was driven by a small locomotive engine—the wheels of which were taken off—that had been used for road-inspecting purposes.

About the time first mentioned the firm of Adams & Co., of the Bow Works, got into some little difficulties; and as it appeared to me that the fish-joint patent was likely to become of value, Mr. Jos. Samuel agreed, and did pay, Mr. W. Bridges Adams, or his brother, Mr. Charles Adams, the sum of £2,000 for his entire interest in his patent, which was paid, and the patent became the joint property of Mr. Robert Richardson, Mr. Samuel, and myself, for having had a very considerable share in perfecting the invention. I applied to the two gentlemen before mentioned for my due share in the profits arising, or likely to arise, from the improved suspended joint; and, as a proof of the reasonableness of my claim, I may mention that Messrs. Richardson and Samuel assigned over to me one-sixth share in the patent relating thereto, which I herewith submit to you for inspection.

You have my full permission to make whatever use you please of this communication.

I forward you tracings of Adams' and Richardson's patent wedge-joint, and the after improvement carried out by myself.

I am, dear Sir, truly yours,
(Signed) PETER ASHCROFT.

HISTORY OF DECARBURIZING IRON.

No. IV.

FURNACE FOR REFINING IRON.

JOHN C. McMANAWAY, Scioto, O.—1842. June 22. (U. S.)

NOTE.—*No specification published.*

FURNACE FOR PUDDLING AND REFINING IRON.

PETER COOPER, assignee of JOHN S. GUSTIN, New York.—1842. August 22. (U. S.)

NOTE.—*No specification published.*

PUDDLING FURNACE WITH HEATING CHAMBER.

BODMER, JOHN GEORGE.—1843. Oct. 5. No. 9,899.

This patent is for to nine distinct inventions; that referring to the subject under consideration is as follows:

7th. A double furnace is constructed, having one fire-place in front, while the back part is divided by a horizontal division or shelf into two compartments, an upper and a lower one, each having its own bridge, and each connected with a separate chimney. The lower compartment serves as for the puddling process, and when that is completed its chimney is closed with a dampei, and while the balls are being made and removed, all the blast flames and heat pass into the upper compartment, where the iron undergoes "a kind of refining process," and is afterwards dropped down into the puddling compartment, through a slot in the upper bridge. The improved movable grate (described in the 4th section of the patent), may be applied to puddling furnaces.

[Printed, 1s. 9d. See "Mechanics' Magazine," vol. 40, p. 271; and "Engineers' and Architects' Journal," vol. 7, p 153.]

NOTE.—*The function of the upper chamber can be hardly anything but* HEATING, *or perhaps partially melting, the iron preparatory to puddling. See Gardiner's patent of* 1788. (*Van Nostrand's Magazine, No.* 4, *page* 358.)

FURNACE WITH A LOW GRATE, THE BLAST INSTEAD OF DRAFT, AND HOT AIR FORCED IN ABOVE THE FIRE—ALSO REFINING BY JETS OF HOT AIR.

DETMOLD, JULIUS ADOLPH.—1843. Oct. 18. No. 9,911.

Improvements in "furnaces or fire-places," &c. The invention is intended to obviate the disadvantages arising ' from the formation of combustible gases in the furnace, and the passing of undecomposed air through the grate," and also from cold air being "drawn into the furnace through the door when open, and through every opening or crevice" in the furnace.

These objects are to be effected, 1st, by making the grate much deeper than ordinary, from three to five feet, according as the coal is caking and bituminous, or light in quality.

2d. Instead of relying on the draft of a chimney a blast is forced into the ash-pit below the grate (the ash-pit having an air-tight door), and up through the grate. The body of fuel, except the stratum immediately above the bars, will not be maintained at a high heat, and all that is combustible in the fuel is converted into combustible gases.

3d. The "combustion of these gases" is effected "by forcing amidst them, in their passage over the fire bridge, heated and compressed atmospheric air" supplied from pipes heated in the chimney, and regulated by valves, and introduced through a row of tweers placed in front of the bridge. The pressure of the air within the furnace must always exceed that of the atmosphere. Any kind of coal may be used, and anthracite is particularly beneficial. These closed furnaces are specially adapted for the manufacture of iron; and the specification and drawings describe how they are to be worked. In refining iron, a blast of hot air is directed on the iron through tuyeres converging towards the center of the hearth, and having a pitch of twenty-five or thirty degrees. Iron may be advantageously refined and puddled in the same furnace.

[Printed, 11d. See "London Journal" (Newton's), vol. 25 (conjoined series), p. 73; and "Mechanics' Magazine," vol. 40, p. 379.]

NOTE.—*Mr. C. E. Detmold patented an improved furnace in the United States, April* 16, 1842, *but no specification is accessible.*

The merits of hot-air jets, PROPERLY APPLIED, *above the fire, are hardly appreciated yet. In some of our forges they are used with success for heating, and save much fuel, for instance, at the West Point Foundry. They form a leading feature in the furnace used for the Pomeroy process.*

This is the first mention of the use of BLAST, *instead of the natural* DRAFT, *in the patent records—now a distinguishing feature of the American, as compared with the English practice.*

PURIFYING LIQUID IRON BY SCRAP IRON, BITUMINOUS SUBSTANCES, NITRE AND OTHER FLUXES, AND BY CURRENTS OF ELECTRICITY.

WALL, ARTHUR.—1843. November 18. No. 9,946.

"Improvements in the manufacture of iron." The operations are divided into two classes.

1st. While the iron is in a state of fusion, two compounds (A and B) are added to it. A consists of a mixture of steel or iron filings or cuttings and rosin, two pounds of cuttings to five pounds of rosin. These are made into balls of five pounds weight each, and are thrown on the iron when in a state of fusion in the smelting or other furnace, in the proportion of one ball to five hundredweight of iron. Instead of rosin, analogous substances, pitch, tar, &c., may be used; a few pounds of charcoal may also be added to the ball. B consists of a mixture of salt, rosin and charcoal (of which the proportions are not given), and is to be added after A has been applied, in the proportion of one pound of mixture to one hundredweight of iron. Instead of salt, other fluxes, nitre or fixed alkalies may be used.

2d. When the metal is "congealing" or solidifying, electric currents are to be passed through it in every possible direction.

[Printed, 3d. See "London Journal" (Newton's), vol. 21 (conjoined series). p. 426; and "Engineers' and Architects' Journal," vol. 7, p. 197.]

NOTE.—*This is the first mention of nitre, now used in the Heaton process.*

BLOOMERY.

SIMEON GUILFORD, Lebanon, Pa.—1843. December 27. (U. S.)

Forge, bloomery, for making wrought iron.

NOTE.—*No specification published.*

PURIFICATION IN PUDDLING, BY SULPHUR(!), NITRE, BORAX, ALUM, SODA AND POTASH, IN DEFINITE PROPORTIONS.

SOUTHALL, THOMAS, and CRUDGINGTON, CHARLES.—1844. February 8. No. 10,038.

"Improvements in the manufacture of iron." These consist in treating iron when in a melted state, while being manufactured into malleable iron, with a mixture consisting of equal parts by weight of sulphur, nitre, borax and alum, with half a part by weight of soda or potash, or one and one-half pounds of the mixture must be mixed with about four hundredweight of iron, in the puddling furnace, if the iron be intended to be converted into malleable iron. If the iron be intended to be converted into steel. it is said that four pounds of the mixture will be required for four hundredweight of iron.

[Printed, 3d See "Repertory of Arts," vol. 6 (enlarged series). p. 244; and "Engineers' and Architects' Journal," vol. 7, p. 321.]

PURIFICATION IN PUDDLING, BY DEFINITE PROPORTIONS OF OXIDE OF MANGANESE, PLUMBAGO, CHARCOAL AND SALTPETRE.

LOW, CHARLES.—1844. May 25. No. 10,204.

Improvements in making iron and steel. The patentee makes a mixture consisting of about 42 lb. of black oxide of manganese, of plumbago 8 lb., wood charcoal 14 lb., saltpetre 2 lb. These materials should be ground fine and well mixed. The mixture is introduced into the furnace in proportions of about 66 lb. of mixture to every charge calculated to produce 480 lb. of metal. The mixture is to thrown on the iron in the puddling furnace two or three pounds weight at a time, and stirred up with the metal until 66 lb. are used, or until the iron is brought to nature. The mixture may be advantageously used in the above proportions, or nearly, in any of the processes of making iron.

In manufacturing cast steel from malleable iron, two or three pounds of the mixture are to be put in the melting pot "to every 30 lb. of cast steel;" or the ingredients may be added in the same relative proportions to the malleable iron while it is being made. "Then the application of a moderate heat will fuse the iron in contact with the mixture, and convert it into cast steel."

[Printed, 3d. See "London Journal" (Newton's), vol. 26 (conjoined series), p. 17; "Mechanics' Magazine," vol. 42, p. 109; and "Engineers' and Architects' Journal," vol. 8, p. 90.]

ORE AND SCALE MIXED WITH CARBONACEOUS MATTER AND USED IN THE PUDDLING FURNACE — SUBSTANCES CONTAINING ALUMINA USED TO CURE RED-SHORTNESS.

RUSHTON, THOMAS LEVER.—1844. June 21. No. 10,233.

"Improvements in the manufacture of iron." The "hammer slack, rolled scale, red ore, calcined ore and other oxides" usually mixed with iron in the puddling furnace, are mixed with pulverized carbonaceous matter in the proportion of "17 up to (but not including) 28 per cent of carbonaceous matter." The proportions of 28 per cent and upwards being claimed by William Clay. (See Patent. —1840. March 31. No. 8,459.) "To 480 lb. of No. 4 pig iron" the patentee adds "84 lb. of Lancashire hematite ore pulverized and mixed with 20 lb. of powdered coke." If the proportion of hematite be increased, that of coke must also be increased.

"Clay, argillaceous ironstone, or other substances containing alumina," ground fine, are to be added to those ores likely to produce "red short" iron, to cure that defect. in proportions of from four to ten per cent by weight of the ore employed.

A mixture in proportions of about 150 lb. of tap cinder containing 71 per cent of protoxide of iron to 150 lb. of Lancashire hematite, 50 lb. of ground Wortley fire-clay, 50 lb. of chalk, and 100 lb. of coke dust, may be advantageously combined and manufactured, either with or without pig or refined iron, in reverberatory furnaces, into malleable iron.

[Printed, 4d. See "Mechanics' Magazine," vol. 42, p. 122; "London Journal" (Newton's). vol. 29 (conjoined series), p. 103; and "Engineers' and Architects' Journal," vol. 8, p. 54]

NOTE.—*The patent of Mr. Clay's referred to is for making malleable iron in a reverberatory furnace, from fine ore mixed with 28 per cent and upwards of pulverized carbonaceous matter. The specification, however, says: "Pig or scrap iron, of a weight equal to that of the ore, may be added with advantage in the furnace, at the time when the ore and fuel are well heated."*

This patent is interesting now, in view of the experiments making and claims set up, for mixing the ore with carbonaceous matter in the Ellershausen process. More carbon than the iron can supply, is necessary to reduce the ore, and the refuse of coal oil refineries is said to be the best carbonaceous material.

SPECIFIED PROPORTIONS OF SALT, LIME AND IRON SCALES USED IN THE PUDDLING FURNACE.

OSBORNE, JOHN JAMES.—1845. Jan. 16. No. 10,470.

"Improvements in the manufacture of iron and steel, and in furnaces to be employed in such and similar manufactures."

To improve the quality of the iron, "a mixture composed of 2 lb of common salt, 2 lb. of fresh burnt or quick lime in powder, and 15 lb. of iron scabs" or hammer slag is introduced into the puddling furnace in small quantities at a time, and melted up with the charge of about 3 or 4 hundredweight of pig iron. The iron is then puddled and made into bar iron. "For making shear steel," to a charge of 5 hundredweight of pig iron, 20 lb. of hammer slag are added while the iron is liquid, and, subsequently, a mixture of "2 lb. of common salt, 2 lb. of quick lime in powder, and 2 lb. of pearlash, or 4 lb. of the common carbonate of soda" (the former is preferred) should be added in small quantities. A violent effervescence ensues, and the mass, when worked, is made in the ordinary way into shear steel. When cast steel is required, the mass is similarly treated with the mixture, but not puddled or balled; or a blast furnace may be employed. The charge is run out in a plate of about $1\frac{1}{2}$ in. thickness. It is cooled with water, the slag is removed, and then the mass is broken up and melted in crucibles. "28 lb. of the plate, with $1\frac{1}{2}$ lb. of green bottle glass, 8 oz. of pearlash or 16 of carbonate of soda" and "8 oz. of black oxide of manganese," will produce excellent cast steel.

The improved steel furnace is then described.

[Printed, 6d. See "London Journal" (Newton's), vol. 27 (enlarged series), p. 94; and "Engineers' and Architects' Journal," vol. 8, p. 331.]

DECARBURIZING MELTED PIG IRON BY MEANS OF MALLEABLE IRON SCRAP.

HEATH, JOSIAH MARSHALL.—1845. August 4. No. 10,798.

"Improvements in the manufacture of cast steel." The invention is described as an improvement on that of Mr. Heath, patented April, 1839. (See Van Nostrand's Magazine, No 5, page 459.) The decarburation of pig iron may be better effected in an apparatus distinct from that in which it is melted. The pig iron is melted in a cupola or other furnace, and run from it at the highest possible degree of temperature, into a refinery or other receptacle capable of resisting very great heat. The receptacle is to be maintained at a high temperature by means "of currents of ignited carbonic oxide gas" and of heated atmospheric air, or by oxyhydrogen or oxygen gas, or other suitable means. "In order to decarburate the fluid iron in the receptacle" to the proper degree, the necessary quantity of malleable iron must be mixed with it "more or less," as the steel is to be "softer or harder. If cast steel of medium hardness be required" equal proportions of pig and malleable iron answer best; but these vary according to the quality of the iron; gray iron requires more malleable iron than white.

To form a judgment, small samples should be taken out, and when cold tested by fracture. The malleable iron may be mixed in the form of scraps, or by preference in a granular form, produced by reducing a pure oxide of iron to very small fragments, and submitting them to the process of cementation, mixed with just that proportion of carbonaceous matter which is sufficient to combine with its oxygen at a red heat in a close vessel; the malleable iron at a white heat is then mixed with the fluid pig iron, and the whole is stirred and kept in a state of fusion. A vitreous flux should be used to defend the surface from the atmospheric air. The assays taken from the fluid mass will show when the steel is of the required quality, and it is then run into molds.

[Printed, 7d. See "London Journal" (Newton's) vol. 29 (conjoined series), p. 230; and "Patent Journal," vol. 1, p. 386.]

NOTE.—*Heath mentions introducing currents of heated air into a finery or receptacle in which the use of fuel is not specified. Here are some of the elements of the Bessemer process, but there is no further intimation of blowing the air* THROUGH *or* INTO *the molten iron, than that a finery is employed. Partial decarburization in a finery, by air blasts, was very old in* 1845. *The fact that Heath specifies such extraordinary and costly means of keeping his decarburizing vessel hot, indicates that he did not know that simple streams of air blowing through the iron would accomplish both the heating and the decarburization of the iron.*

Melting down or keeping in a state of fusion, in a highly heated vessel or furnace, cast iron and wrought iron scrap, to produce cast steel, appears to be similar to the Martin process, of which the particulars are given in another column.

The use of malleable scrap in decarburizing crude iron, was first specified by John Wood, in 1761. (*Van Nostrand's Magazine, No.* 3, *p.* 194.)

PUDDLING BY AID OF AIR OVER THE FIRE; ALSO BY THE AID OF ORE, SCALE AND SLACK COAL.

BOVILL, GEORGE HINTON.—1846. Jan. 31. No. 11,065.

Improvements in the manufacture of iron. The invention relates to various matters, among others:

5th. To a method of puddling iron "by the application of the water furnace, commonly known as Kymer and Lighton's furnace, the same being worked by air blown into a closed ash-pit, and the introduction of air over the fire to consume the gases generated."

6th. To a preparation of cinder foom Cumberland ore or hammer scale, and the slack of anthracite coal or other suitable fuel, "to assist the working of iron in the puddling furnace," and also to facilitate the combination of steel with iron.

[Printed, 3d. See "Patent Journal," vol. 1, p. 179.]

FURNACE FOR AND PROCESS IN MAKING MALLEABLE IRON.

WINSLOW, JOHN F., Troy, N. Y.—1846. March 16. (U. S.)

NOTE.—*No specification published.*

THE USE OF ANTHRACITE COAL IN THE REFINERY FURNACE.

CRANE, PATRICK MOIRE.—1847. April 8. No. 11,653.

"Improvements in the manufacture of iron." These relate to the use of anthracite coal in the refinery furnace. The anthracite is to be previously heated in kilns or in any convenient manner, or used in a state of ignition. It may be used alone, or mixed with other fuel, and effects saving, and is said to improve the quality of the refined iron.

[Printed, 3d. See "Repertory of Arts," vol. 10 (enlarged series), p 306; "London Journal" (Newton's), vol. 31 (conjoined series), p. 277; and "Patent Journal," vol. 3, p. 529.]

CHARCOAL MIXED WITH IRON IN PUDDLING, AND CASTING INTO PIGS FROM AN AIR FURNACE, INSTEAD OF USING THE FINERY.

BLEWITT, REGINALD JAMES. — 1847. May 27. No. 11,723.

"Improvements in the manufacture of malleable iron." The iron, instead of being refined in a refinery furnace, is to be produced from the air furnace commonly used for casting or founding purposes. It is to be melted in the air furnace, and then run out into sand or iron molds, and then subjected to the puddling process. The fuel used by the patentee "is a white-ash semi-bituminous coal of excellent quality." He uses one or two hundredweight of charcoal with each charge of iron of about four tons.

[Printed, 3d. See "Repertory of Arts," vol. 10 (enlarged series), p. 354; "Mechanics' Magazine," vol. 47, p. 552; "Patent Journal," vol 4. p. 30; and "Engineers' and Architects' Journal," vol. 11, p. 46.]

PIG IRON MIXED WITH FORTY PER CENT OF WROUGHT IRON IS MELTED, "SHOTTED" IN WATER AND PUDDLED—OXIDE OF MANGANESE INTRODUCED THROUGH THE FINERY TUYERES.

VICKERS, WILLIAM.—1847. June 19. No. 11,759.

"Improvements in the manufacture o firon." Pig iron is melted with small quantities of wrought iron, such as scrap turnings or filings, and the mixture is run in finely divided streams into water. The proportions vary; for making good ordinary wrought iron, 30 parts of wrought iron turnings, with 70 parts by weight of iron, are found beneficial. If the iron be intended for making steel, the proportion of wrought iron may be increased, and 40 per cent of wrought iron employed. The melted iron is run into a cast iron tray, perforated with half-inch holes, and lined with clay about ½ inch thick, punctured "with holes about ¼ of an inch thick at those places where there are holes in the tray." The iron is dropped in a divided state into a cistern of water about 15 feet below it, and is afterwards worked up into wrought iron in the ordinary way. From three to five per cent of black oxide of manganese may be used advantageously with the melted pig and wrought iron, and may be introduced by placing small quantities in the tuyere holes.

[Printed, 3d. See "Repertory of Arts," vol. 13 (enlarged series), p. 243; "London Journal" (Newton's), vol 31 (conjoined series), p 427; "Mechanics' Magazine," vol. 47, p. 631; and "Patent Journal," vol 4, p. 127.]

THE NEW BRIDGE OVER THE SCHUYLKILL.—The first premium for designs for a bridge at the site of the present suspension bridge over the Schuylkill, has been awarded to Mr. J. H. Linville. The clear span is 340 ft., width 50 ft., including two sidewalks of 8 ft. each. There are two roadways, the upper one being reached by approaches on iron columns, to avoid grade crossing, over the Pennsylvania Railway at West Philadelphia.

THE PROGRESS OF LIQUID FUEL.

From a paper read before the Institute of Naval Architects, by Captain Selwyn, R. N.

No one here will probably be prepared to deny that economy is the order of the day, and I am here to-night to continue from last year, before the Naval Architects' Institute, the history of liquid fuel, and to insist again on the important economy to be derived from its employment in steam ships especially. The experiments on which I was last year at this time engaged, and to which I then referred as taking place in a small steam launch, terminated in ample proof being given that they had not been unwisely undertaken by the Admiralty at the request of Mr. Reed. During a trial of 7 hours 40 minutes with coal, a small boiler fitted to the launch in question evaporated 5,418 lb. of water at the rate of 8.5 lb. of water (from 212°) per pound of fuel, while with oil the evaporation in the same boiler was 12.3 lb. of water per pound of fuel, and the quantity 3370 lb. in 3 hours 45 minutes.* It is to be remarked that the coal was the best navigation steam coal, and the fire was forced as much as the stoker could do it, but this was not done with the oil, because, the boiler being short, too much heat was already lost up the funnel, no more coal could have been burnt, nor could the quantity then burnt have been continued without frequent cleaning of the fires. The oil, on the contrary, was burning as well at last as at starting, and there was no deposit in the furnace or boiler flue. The fire was lighted with wood, or wood and coal, and oil was turned on as soon as 10 lb. of steam were obtained. The steam was generally raised to 90 lb. pressure in about one hour from lighting the fire. There was no smoke, and a white handkerchief could scarcely have been dirtied in the furnace after the oil fire was put out.

The results were so far satisfactory that the Admiralty gave a larger boiler, which had formerly belonged to the Oberon, and sanctioned further experiments. These are still proceeding, though intermitted for a time from causes over which I have no control. I trust they will shortly be resumed. The boiler in question is nominally of 130 horse power, and with coal has evaporated on trial in July 206 cubic feet of water per hour, making her equal on the allowance used at

* Mean per hour :
Coal, 100 lb. .... 706 lb. water.
Oil, 100 lb. .... 1032 lb. water.

Woolwich of half a cubic foot per horse-power to a real power of 412. On that trial she burnt in three fires 13¾ cwt. of coal per hour, and evaporated at the rate of 8.2 lb. of water per lb. of fuel burnt. Now, it may here be observed that it is extremely doubtful if this rate of evaporation could be maintained for any very long time in practice with coal in this boiler. There is, on the other hand, no doubt whatever on my mind, or, I think, in that of any one who has seen the liquid fuel in operation, that whatever it does once it will continue to do for any number of hours or days, if the same quality of oil be used, and the furnace be not altered purposely, because there is no stoking needed, and no deposit of any kind to require removal. The boiler was prepared to burn the oil in the following manner: having been already placed on the wharf of the steam basin for a previous experiment not connected with these, it was only necessary to fill the tanks which were on the top of the boiler with oil, to have them correctly gauged, and to fit a pipe to convey the oil from the tank to the fire-doors, where it entered the injector. Steam was taken from a small boiler placed near the large one, and fired with coal, and by another pipe this was brought to the fire-doors, thence through a superheating coil in each furnace, and, lastly, into the injector, where it met the oil. The boiler was a tubular one, with twelve rows of tubes. These were divided by diaphragms in the combustion chamber and smokebox into three runs as follows: a diaphragm of ½ in. iron plate was pierced full of holes, and then lodged in the combustion chamber, over the fourth row of tubes, thus forcing the products of combustion to return through the four lower rows of tubes alone. Arrived in the smokebox, the heated air met another diaphragm exactly similar to the first over the eighth row of tubes, which forced it to return again to the combustion chamber through the tubes left open to it. From thence it again pressed back to the uptake through the upper four rows of tubes. The object of the holes in the iron diaphragms above spoken of was that fireclay might be plastered on the plates above and below, and be jointed through as it was thought the heat would otherwise soon cause the plates to lose their shape and bend down. It is clear that had they been designed for anything more than an experiment, there should have been water spaces. But as far as the oil burning was carried, the heat seemed to be sufficiently kept down in these plates by contact with the water spaces of the boiler. No attempt has yet been made to ascertain what quantity of water can be evaporated by this boiler with oil, since it was soon discovered that the small boiler could not, evaporating from 3 to 4 cubic feet only of water, supply steam enough to burn the full quantity of oil. It was first necessary to find out the best arrangement of furnace, and this could be done while burning only a small quantity of oil per hour. As the size of injector, its best arrangement, and the quantity of steam required per pound of oil to produce the best effect, were also matters for preliminary experiment, these were the first points to which attention was given. It was found that the oil could be perfectly burnt, as you will see by the tabulated result, without removing the firebars, or in any way altering the furnace so as to prevent coal being burnt the next hour if desirable. That the form of injector giving the best effects was that where the oil was in the internal injector with the steam issuing from an annular aperture round it. That the quantity of steam required for jets would be about 1 lb. per pound of oil burnt. That rough broken firebrick, or whole firebricks, loosely built up on the firebars, were perfectly efficient as governors and distributors of the intense heat generated by the combustion of the oil. These speedily got nearly white hot, and remained so. That the superheaters should be placed in the smokebox preferably to the top of the furnace, where they had been fixed, as giving rise to the least alteration of the ordinary state of the boiler for coal. That the firedoors ought to be made in a different form, *i. e.*, box doors opening with a regulator, and hung from above instead of at the side, and that some other slight modifications would be desirable, though not necessary.

The whole arrangement was then altered in order to establish whether by lining the furnaces with firebrick after taking out the firebars, building up bridges, etc., any better result could be obtained without any diaphragms, which were also taken out.

This part of the experiment has not yet been finished, and I am not, therefore, prepared to give any further information about it now; but I hope to try it thoroughly, since it was under a modification of this arrangement that the extraordinary results I narrated last year seem to have been obtained. The oil supplied during these preliminary trials has been analysed by Professor Church, of Cirencester College, with the following results. It is composed of

Carbon...;............	86.48
Hydrogen...............	7.06
Oxygen, or refuse........	6.46
	100.00

Now, referring to Professor Macquorn Rankine's admirable paper, we find that, in order to arrive at the calorific effect in British units of heat to be expected from this oil, we have to make the following simple calculation :

	Per cent.	
Carbon.....	86.48 × 15 =	13.02
Hydrogen...	7.06 × 64 =	4.5
Total...............		17.52

if refuse be not oxygen ; or,

Carbon....	86.48 × 15 =	13.02
Hydrogen..	6.26 × 64 =	4.00
Total...............		17.02

if refuse were oxyen, deducting $\frac{1}{8}$ its weight of the hydrogen. Thus, in either case we may say that the total theoretical evaporative duty or calorific effect in pounds of water evaporated from 212° Fahr, is 17 or 17.55 respectively. Now the next calculation, taking the figures from the tabulated result at Woolwich, is to be performed thus :

Temp. of feed, 50° Fahr. ; temp. of actual boiling point due to 26 lb. pressure, 269° T b ; const., 212° ; boiling point, T^1. Now the formula is thus :

Evaporation reduced or corrected = evaporation observed ×

$$\frac{1 + T^1 - T f + 0.3 \text{ of } T b - T^1}{966^\circ \text{ Fahr.}}.$$

Then

$$\begin{array}{ll} T^1\ 212^\circ & T\,b\ 269^\circ \\ -T\,f\ \ 50 & -T^1\ \ 212 \\ \hline 162 & 57 \div 0.3 = 17.1 \\ +\ \ 17.1\tfrac{3}{10} \text{ of } T\,b - T^1 & \\ \hline 179.1 \div 966^\circ = .18. & \end{array}$$

Then unity + .18 = 1.18 × evaporation observed at feed temperature 14.22 = 16.77 lb. of water evaporation from constant of 212° Fahr. by 1 lb. of oil against 17.52 total duty to be expected from this particular sample of oil. If other oils capable of giving up to 22 lb. or 24 lb. of calorific effect be operated on, we may expect an equally satisfactory approach to their theoretic value.

It is to be observed that the sample taken for analysis was from the last of the oil, and as we may expect that the whole quantity would be arranged according to specific gravity, perhaps this, which was one of the first trials, got a little advantage in that way, but there could not have been more difference than 1 lb. of calorific power either way.

I would draw particular attention to the fact that during this trial the temperature of the bottom of the funnel was so low as 120° Fahr. I must now point out that the rule adopted throughout the Government trials of calculating the evaporative effect from a constant of 100° Fahr,, though fair enough for comparison at ordinary temperatures and pressures, does not take into account the latent heat due to high pressure in the boiler, neither does it give in any way the actual calorific effect of the fuel in British units of heat, which Professor Macquorn Rankine's formula does.

I have also to observe that in buying oil for heating purposes, as much attention ought to be paid to the chemical analysis showing the proportions of carbon, hydrogen, refuse or oxygen (if any,) as would be done with coal to ascertain from which mine or stratum it was obtained, and consequently what effect it might be expected to produce. There will also be a necessity for a specific gravity and fire test, as adverted to in my former paper.

I will now briefly advert to some other independent proofs of the calorific effect of these oils, as compared with coal.

A boiler plate furnace at Woolwich has been fitted to burn oil after the process patented by Messrs. Dorsett and Blyth, which first converts the oil into gas in a species of retort, or still resembling an ordinary vertical boiler of small size, and then burns it as gas issuing from small apertures in a coal of iron pipe. Here no steam is required ; but I have seen reason to think that in a ship the other apparatus will be preferable, as I do not think there is much, if any, difference in the calorific results, and in the plan I now, use only the oil and steam pipes with the injector are necessary.

However this may be, the results obtained in this furnace, which now burns oil instead of coal, are briefly these :

Seventy-five gallons of oil are used per day, instead of 1 ton of coal, or the sp. gr. of the oil being 1,050 about 780 lb. of oil heat the furnace, which had required 2,240 lb. of coal. This gives us a proportion of 1 to 2.7. But this is not all. The ½ in. iron plate which took formerly 15 minutes to heat now takes 6; thus effecting a saving in time, which those who have seen men waiting round a furnace for the heat to be got on, will do well to appreciate; the proportion here is 1 to 2.5. Now, 780 to 2,240 is 2.7 times the duty of coal, or equal, if we take coal at 7 lb. of water evaporative power to 18.9 lb. of water evaporated by 1 lb. of oil. I am informed that a still more remarkable difference was observed in the time taken to heat armor plate when a small piece of it was tried. The heat is remarkably even and free from scale, and no difference has been observed in trials made as to the usual tests for strength after heating. Since last writing on the subject, several other boilers and retorts have been fitted to burn oil, and are giving satisfaction; but where the proper flame has not been obtained, *i. e.*, the blue glow due to burning carbonic oxide, the results always fall short of the true value of the oil, though still showing a considerable superiority to coal. As regards danger, I will repeat the experiment made here last year with a burning fuse.

But the best answer is to be given by those who have had it in practical operation during the past eighteen months without any accident. It is perfectly true that a gas explosion, though not a very dangerous one, resulting in the singeing or burning the faces of those who do it can be produced, if while there is no flame in the furnace, the oil be allowed to drop on the hot bricks till gas is made sufficient to mix explosively in the furnace with air; and I know one gentleman who has recently insisted on trying this for himself, against his engineer's advice, and who got conclusive evidence of the fact in singed whiskers and a slightly scorched face. One such explosion also took place at Woolwich at the close of a successful day's work in my absence; but there, also, those who did it confessed that it was entirely their own fault, and were not at all afraid of going on afterwards.

If I were to use any process for making the oil into gas before using it, I should prefer, on many accounts, to do this by means of Perkins's coil of hot-water pipe (used some years ago in this city for baking bread), instead of putting a fire under the still.

IMPURITIES IN IRON.

From a paper "on the Molecular Action of Impurities in Iron," read before the Philosophical Society of Glasgow by Thomas Rowan, F. C. S., F. R. S. S. A., Atlas Works, Glasgow.

The impurities contained in iron and steel, such as phosphorus, sulphur, &c., which injuriously affect the good qualities of these metals, have of late been the subjects of much discussion and elaborate investigation. Without wishing to enter into the discussion as to the effects produced by certain quantities of these impurities, I would suggest that these effects may not be entirely dependent on the presence of any one element known to produce them in greater or less degree, but may be intensified or modified by *combinations* of impurities in the same metal. Thus the alleged absence from the Heaton steel analysed by Dr. Miller of the cold shortness which under ordinary circumstances would be due to the amount of phosphorus which it contains, may be occasioned by the presence of the calcium, etc., shown in the analysis. I conceive these results to be due to molecular change, which is variously produced in the iron or steel by these various elements, each element acting in a definite manner on the molecules of the metal, while in some instances the action bears a relation to that produced by some other meterial.

It seems clear that iron and steel are capable of numerous modifications or changes of their molecules or particles, by which different physical properties may be imparted to the same bar or piece. Some of these which are produced by mechanical means, are well known in their general effects. For instance, if Bessemer steel in its cast state be struck violent blows with a hammer it undergoes a disintegration similar to that which is produced in metal possessing the quality of "red shortness," while if the same metal be first hammered gently it will afterwards withstand successfully more violent treatment than that sufficient to disintegrate it in its former state. Again, it is well known that a considerable degree of *hardness* is imparted to blister steel by dipping it, when hot, into cold water, the chemical composition of the bar nevertheless remaining entirely unaltered. The converse result, or the impartation of softness to a hardened steel bar, can also be obtained by mechanical means. A somewhat similar instance of the alteration of molecular structure by mechanical means is to be found in the familiar operation of "chilling," by which certain parts of a casting, which are exposed to this action, are materially altered in internal structure, and have in some cases an extraordinary degree of hardness imparted to them, this quality not being possessed by the metal in its original state, nor, of course, by the other parts of the casting not so treated. In the first of these instances the molecules or particles of Bessemer steel seem to have in its cast or crude state such positions relatively to one another as to cause them to *separate* under the influence of heavy hammering, while under the gentler blows they rearrange themselves, and are induced to take up positions conducive to the strength and toughness ultimately possessed by the manufactured bar.

Some interesting experiments on the action of heat in producing a molecular change in iron wire have been made by Mr. G. Gore, F. R. S., and communicated by him to the Royal Society.*

Mr. Tresca, in a paper on the "Flow of Solids," read before the Institution of Mechanical Engineers in Paris in 1867, thus speaks: "The structure of iron, as composed of contiguous filaments appears to afford an explanation of the causes of the transformation of fibrous iron into crystalline iron after long use; filaments of different natures may also differ in hardness, and the facets seen in the fracture of crystalline iron are nothing but surfaces caused by friction between the particles, arising in the molecular vibrations and consequent elastic changes of form to which iron may be subjected, according to the use it is put to. These facets should never be mistaken for the grain in the iron, which is originally nonfibrous; and an examination with a magnifying glass shows that there is in fact no similarity between the two states." This author also states that he has produced numerous facets by twisting and untwisting the same specimens of granular iron a number of times.

It is to similar molecular action, resulting, however, in these instances from *chemical force*, that I would refer the effects produced on iron and steel by the presence of the various elements denominated "impurities." Thus phosphorus would, on this supposition, be found to act on the molecules of pure iron by inducing a permanent formation or relative grouping of them, which in result corresponds to the quality of "cold shortness" in the metal. Sulphur, while similarly acting on the molecules, would induce a different arrangement of them, and consequently different results would accrue to the metal.

We could understand that in these two instances, the results being nearly opposite, the relative formations would be found to have nearly opposite characters also. It might on this theory be possible, were the effects observed which are produced by various elements, to modify or intensify at will any particular class of characteristics in any given substance; although it is very improbable that any one class of effects could be counteracted by the production in the same metal of those of an opposite class. In case of such combinations a new condition would in all probability result from the complex character of the internal action.

Some careful examinations of the structure of different classes of iron, which are very valuable in their results, and calculated to throw some light on this subject, have been made by M. Schott, of Ilsenburg, and are published in a work on "Iron and Steel Manufacture," by F. Kohn.

M. Schott made microscopical examinations of the fractures of various qualities of cast iron, and also minutely examined the appearance afforded by those irons when passing from the liquid to the solid state. He has also made numerous examinations of the structure of steel, and, as the result of all his researches, maintains that "all crystals of iron are of the form of a double pyramid, the axis of which is variable, as compared with the size of the base. The crystals of the coarser kinds, as compared with those of the finest qualities of crystalline iron, are of about twice the height. The more uniform the grain, the smaller the crystals, and the flatter the pyramids, which form each single element, the better is the quality, the greater is the cohesive force, and the finer the surface of the iron. These pyramids become flatter as the proportion of carbon contained in the steel decreases. Consequently, in cast iron and in the crudest kinds of hard steel the crystals approach more the cubical form, from which the octahedron proper is derived, and the opposite extreme or wrought iron has its pyramids flattened down to parallel surfaces or leaves, which in their arrangement produce what is called the fibre of the iron. The highest quality of steel has all its crystals

* (See *Proceedings* of the Royal Society, No. 108, January, 1869.)

in parallel positions, each crystal filling the interstices formed by the angular sides of its neighbours. The crystals stand with their axes in the direction of the pressure or percussive force exerted upon them in working, and consequently the fracture shows the sides or sharp corners of all the parallel crystals. In reality, good steel shows, when examined under the microscope, large groups of fine crystals like the points of needles—all arranged in the same direction and parallel."

It is thus evident that the presence of other elements or impurities affects, in greater or less degree, the regularity of the structure of iron; and I have little doubt that research, by determining the method of their action upon the molecules of the metal will place its qualities more under control.

THE DARIEN CANAL.

The following abstract of the report of Messrs. McDougal and Sweet, the engineers who surveyed the route of the "San Blas Ship Canal" in 1863, is compiled from a resumé of the report, as prepared for the "Syracuse Daily Courier" by Mr. Charles A. Sweet, one of the engineers above mentioned. The complete and accurate statistics here presented will be found especially interesting at the present time:

Public attention has long been directed to projects of a grand inter-oceanic ship canal, to connect the two oceans at or near the Isthmus of Panama or Darien, and to decrease the distance now necessarily traversed and diminish the time now consumed in going from the ports of either ocean to the other. To that end grants have, at different times, been made by Central American States, or treaties negotiated with them. Surveys of different routes have been completed, and yet no progress has yet been made towards actual construction beyond the survey and estimates of cost.

The recent negotiation of a treaty between this government and the United States of Columbia, securing and regulating the right to construct a canal across the Isthmus, has now revived the long dormant interest in this project.

The Shortest Route—This is the "San Blas" route, about thirty miles long, its cost to be about sixty-five millions of dollars. The surveys were made in 1863 in behalf of Mr. Frederick M. Kelly and others of New York city, under the direction of A. McDougall, Esq., of Massachusetts, now deceased, as Chief Engineer, and Charles A. Sweet, now of Syracuse, N. Y., as principal Assistant. The report of the Surveyors was made to Mr. Kelly in 1864.

General Features.—The whole exact length of this canal, according to the survey above referred to, is but 30.03 miles. It extends from Chepillo Island in Pacific Harbor, on the Pacific Coast, to the Gulf of San Blas, on the Atlantic side. The entire work is divided into four sections. The first section extends from Chepillo Island to "Paneas," on the Bayano river. Besides a dam across the river, a tidal lock at the Great Bend of the river, and a short cut across the Bend, the work on this section consists chiefly of the removal of sand bars in the harbor and river. It is 10.101 miles long, and consists chiefly of excavation for the canal and largely of rock excavation. At the southern entrance of the tunnel through the mountains, the greatest elevation attained on the first two sections of the canal is reached, being 150 feet above the level of the water surface of the canal, or 175 feet above that of the Pacific. The entire route, except near the mountains, is nearly level. The summit of the Cordilleras, through which a tunnel is to run, is, however, 1,500 feet above the level of the same ocean. The soil is shallow, being loam or sand, with rock below, and only from two to five feet deep. The elevation of the surface of the land above the proposed surface of the canal is but six feet near its southern terminus, and but one foot near its northern. The entire canal is to be fed from the Pacific ocean, and its water to be maintained at the level of ordinary high tide in the Pacific. The tides in the Pacific rise from 12 65-100, the lowest flood tide, to 22 feet for the highest; and these create the necessity for a tidal lock of $45\frac{1}{2}$ feet elevation of wall. The tides on the Atlantic side are insignificant, rising only from one to one and a half feet from ebb to flow. The third section is rock-cutting through the Cordilleras, seven miles long; and the fourth section consists of excavation for canal, similar to the work on the second section, terminated by a lift lock. The whole route is a wilderness, without even a hamlet or village upon it, although four miles from it there is one native village of 2,000 inhabitants. The following is the official estimate of the cost of the work by sections upon the survey and plan above referred to:

SECTION NO. 1 extends from the island of Chepillo through Bayano river, to divergence of the canal from it at Paneas, $10\frac{101}{1000}$ miles.

The river is three miles wide at mouth with 30 feet depth of water.

The work on this section consists—first, of the removal of sand bars in Pacific Harbor and Bayano river; second, a lighthouse at Chepillo Island; third, a tidal lock at Great Bend with walls $45\frac{1}{2}$ feet high; fourth, a composite dam at Great Bend; fifth, completion of the Great Bend cut.

The cost of these several works, including draining, chopping, earth and river excavation, embankment, masonry, labor, materials, &c., is estimated as follows:

Removal of bars	$136,684
Light House	12,000
Tidal Lock	675,844
Composite Dam	174,631
Great Bend Cut	209,835
Total cost section No. 1	$1,208,994

SECTION NO. 2 is a canal from Bayano river at "Paneas" to the south end of the tunnel, and is $8\frac{996}{1000}$ miles long.

The levels to the south end of the tunnel were taken by the late chief engineer, Mr. McDougall; the other levels on the entire route by Mr. Sweet, his principal assistant.

The work on this section consists, first, of construction of canal from its point of divergence from Bayano river, at Paneas to the south end of the tunnel; second, of a new channel for the Mamoni river, which crosses the route of the proposed canal, $3\frac{600}{1000}$ miles long.

The cost of the first named work of this section, including bailing, draining, chopping, excavation, embankment, puddling, &c., is	$13,033,943
The cost of the second is	115,752
Total cost second section	$13,149,695

SECTION NO. 3 is a tunnel through the Cordilleras seven miles long. This work is exclusively rock excavation. It consists of a canal of 25 feet depth of water, a perpendicular excavation of 29 feet above the water surface on either side, whence springs the arch rising 561 feet above its starting point on a perpendicular, making 105 feet from bottom of canal to top of arch. The total cost of this work, at $2.50 per cubic yard, is estimated to be $29,316,067.

SECTION NO. 4 extends from the north end of the tunnel to 25 ft. depth of water in the Gulf of San Blas, Atlantic side, $3\frac{733}{1000}$.

The work on this short section consists—1st, of construction of canal; 2d, of a lock with 9 feet fall and walls $38\frac{1}{2}$ feet high; 3d, a lighthouse on San Blas Point. The estimated cost

Of canal is	$11,234,318
Of lock No. 2, or lift lock	506,017
Of lighthouse	12,000
Total cost of Section No. 4	$11,752,335

GENERAL SUMMARY.—The capacity of the tunnel portion of the canal has already been stated. These estimates contemplate, on either side of the tunnel, the same depth of water as in the tunnel, but a greater width of canal. Beyond the tunnel the surface width of canal is 143 feet, and width at bottom 100 feet. The summary of the total estimated cost of a canal of the above dimensions on this route is as follows:

Section No. 1	$1,208,994
Section No. 2	13,149,695
Section No. 3	29,316,067
Section No. 4	11,759,335
Add ten per cent for contingencies and engineering expenses	5,602,809
Add for medical and military departments, interest upon capital during construction and transportation, etc.,	32,500,000
Total	$93,469.800

A second was made and submitted for a canal of less width and depth of water. For this canal, with a width at water surface of 100 feet, and at bottom of 80 feet, and 20 feet depth of water, the estimate cost is summed up as follows:

Section No. 1	$1,005,565
Section No. 2	10,506,669
Section No. 3	29,147,067
Section No. 4	8,862,008
Ten per cent for contingencies and engineering expenses	4,952,131
Add for medical and military departments, interest upon capital during construction and transportation	25,000,000
Total	$79,473,440

We may add that in the judgment of the surviving engineer, Mr. Sweet, 15 per cent instead of 10 per cent ought in this case to be added to the estimated cost to cover contingencies and engineering expenses.

COMMERCIAL ADVANTAGES AND VALUE OF CANAL.—With the estimates of cost there were submitted also certain statistics to show the great value of this projected canal to shippers and to the public. According to one of these statements, the freight paid at San Francisco, on goods from the Atlantic in 1853 alone, being only a part of the trade, as some freights were paid before shipping, was $9,911,432.

At least three-quarters of this charge would be saved, or $7,433,574, or the interest at 6 per cent on a capital of	$123,892,900
The foreign trade of San Francisco would be benefited by one-half the freight, the amount of which paid at port in 1853 was $1,840,650. One-half is equal to the interest at 6 per cent on........................	15,338,750
The foreign Pacific trade to the United States was carried out in 1854 in 961 vessels outward bound and 895 entered home, showing that the trade is equivalent to more than two-thirds of that of California. It would, therefore, in passing through the canal, make a corresponding saving for a sum equal to..................	99,450,570
Thus showing that the canal would save to the United States alone an annual interest on the sum of	$238,682,220

There is also a table showing the number of vessels visiting the ports of the different countries of the Pacific beyond Cape Horn, the tonnage entering those ports, the tonnage and value of their exports and imports. Without embodying details as to the several countries, we give only totals. The number of vessels was 3,693.

The tonnage of imports was..........	1,682,349
That of exports	1,586,349
Total tonnage..................	3,268,698
The valuation of exports was.........	$49,815,000
That of exports	100,188,000
Total val. of exports and imports,	$150,003,000

There was also attached to the report an interesting table, showing the savings in distance from New York to ten of the principal ports of the Pacific by the route of the contemplated canal over the two Cape routes, which we give in full, as follows:

From New York to Ports.	Distance via Cape of Good Hope.	Distance via Cape Horn.	Distance via Isthmus canal.	Saving in miles over Cape of Good Hope route.	Saving in miles over Cape Horn route.
Calcutta........	17,500	23,000	13,400	4,100	9,600
Canton.........	19,500	21,500	10,600	8,900	10,900
Shanghai.......	20,000	22,000	10,400	9,600	11,600
Valparaiso......	....	12,900	4,800	....	8,100
Callao..........	....	13,500	3,500	....	10,000
Guyaquil	....	13,300	2,800	....	11,500
Panama	....	16,000	2,020	....	14,000
Mazatlan.......	....	18,000	4,000	....	14,000
San Diego......	....	18,500	4,500	....	14,000
San Francisco..	....	19,500	5,000	....	117,700
				22,600	117,700

This shows a saving in the several voyages, one to each of the three ports first named, of 22,600 miles over the Good Hope route, and a saving in a single voyage to each of the ports, by way of Cape Horn, of 117,700 miles.

Colonel Totten, in his report of 1866, on the progress of the Panama railroad, has a condensed table, in which he states that after deducting the British trade with Australia, the aggregate tonnage which doubled Cape Horn to and from the Pacific ports was

In tons............................	2,679,600
There had been an actual increase for the ten previous years of 115 per cent. Estimating a like increase since 1855, we have an increase in addition to the above for the eight years from 1855 to 1862 inclusive of..................	2,465,155
Or a total tonnage of...........	5,144,752

The voyage of a ship of 1,200 tons, off Sandy Hook, with a complete outfit, via San Francisco, via Cape Horn, costs $12,000, including running expenses for 145 days, or

Per day..............................	$82 75
In this amount is included the insurance of 13 per cent on value of ship, averaged at $100,000. In consequence of cheapened insurance because of an avoidance of the Cape voyage, the expense per day by the Isthmus route will be reduced to......	64 70
Or a saving per day of..............	$18 05
The total cost of a voyage of 145 days is..	$12,000
Of that of 60 days by canal.............	3,882
Total saving	$8,118
The cost per ton on a vessel of the above burthen, via Cape Horn, will be.......	$10 00
Cost via Ship Canal....................	3 23
Saving of cost per ton..............	$6 77

Taking the statistics based on the report of our foreign commerce of 1853, we had a total tonnage estimated for 1864 of 5,000,000 tons. The total saving on this amount at $6.77 per ton is $33,850,000. If the saving on insurance on cargo as well as vessel be estimated, the saving to commerce would be about the same as that shown by Mr. Kelly.

Conclusion.—It is evident, therefore, from statistics, that with the rapid development of the trade to and from our Western coast, as well as to other ports on the Chinese and Japan seas and the Pacific ocean, the time has fully arrived for the construction of this long-mooted Ship Canal through the Isthmus of Panama; that its construction cannot fail to be profitable to them who construct it, and still more profitable and beneficent, directly to the commercial world, and indirectly to the whole people who produce the articles of that commerce and to those who consume them. And, further, unless this canal be now speedily opened, the rich trade of the Asiatic coast will soon be largely concentrated, either by the Suez canal in European hands, or diverted to the cities of the Pacific slope, to the great loss of our Atlantic coast.

Mr. Sweet, the principal assistant in the survey, the results of which are here given, has been long connected with the public works of New York. He is a man of great practical experience, skill, and unquestioned integrity, well and favorably known to the profession in this State. These pioneer surveys were partly, and the estimates of work and cost were wholly made by him; and since the death of McDougall, the chief engineer, no man could be found better adapted to conduct and superintend this great work to an economical and successful termination than this pioneer in the original survey.

SCREW VS. PADDLE SHIPS.

Extract from a paper discussing the types of steamships, by Norman W. Wheeler.

The extreme depression of late years endured by the European steam navigation interest has produced the natural results of rendering prominent, and of bringing into somewhat extended use, better and more economical types of ships and marine steam machinery. The practical success attending the efforts of Messrs. Randolph, Elder & Co., and others, in introducing economical principles into steamship practice, may properly be taken as good warrant for the adoption here of the same principles. It affords the writer much pleasure to know that able European engineers have independently worked out and made successful general plans which he has persistently advocated for more than twelve years, and in one instance reduced to successful practice.

Many European steamship companies have altered, or are now altering, such of their old paddle-ships as are deemed worth the conversion, to accord with modern economical systems, and the more prominent and enterprising companies have utterly discarded the old and expensive practice comprising non-expansion, salt feed water, slow piston speed, and very narrow, deep ships. A few instances are noted below contrasting the performance of steamers under the old system with that of the same or like ships under the new, the authority being that of the French Society of Engineers.

The French steamer Europe, 2,200 tons, and 900 nominal horse power, consumed an average of 1,158 tons of coal per trans-Atlantic voyage, the mean speed being 10.75 miles per hour. The St. Laurient, with hull and boilers identical with those of the Europe, consumed 1045 tons of coal per trans-Atlantic voyage, the average speed being 11.9 miles per hour. The engines of the two ships, considered by themselves, are practically equal to each other in economy, and the difference in performance is solely due to the substitution of the screw for the paddle-wheel as an instrument of propulsion. The chief gain in this case is in freight capacity; but the passages are reduced by about seven hours, and 113 tons of coal are saved.

These results decided the proprietors of the line to convert the paddle steamer Washington into a twin screw steamer, with improved engines, but without change of hull or boilers. With the former engines and paddle-wheels, the consumption averaged 96 tons per day, and the speed 10 miles per hour. She now consumes 83 tons per day and averages 11.8 miles per hour.

The commercial gain by the conversion is two days time in a trans-Atlantic voyage, 335 tons of coal per passage, and an increase of freight capacity equal to the coal saved. If she were driven at her present speed by the old engines and wheels, the consumption would be 157 tons per day. If she were driven at her old speed by the new machinery the consumption would be 50 tons per day, making a difference of 46 tons per day in one case, and 61 tons in the other.

The Napoleon III averages 10.58 miles per hour, and consumes 115 tons per day. Messrs. Randolph, Elder & Co., have contracted to convert the ships into a twin screw steamer, with their system of steam machinery, guaranteeing a speed of 12 miles per hour with a daily consumption of 70 tons. To drive this ship at the promised speed with the old machinery would require 167 tons of coal per day, and to drive her at the old speed by the new machinery will require but 48 tons; a difference of 97 tons in one case and 67 tons in the other. * * *

The steam yacht Octavia, the property of Mr. T. W. Kennard, is believed to be the most economical ship extant, and the earliest example of compound engines connected directly to the screw shaft. The hull and engines were designed by the writer, some of the leading features having been dictated by Mr. Kennard. The Octavia is a wooden, single screw steamer of 425 tons displacement at mean draft, fitted with one pair of Wolff cricket engines, with steam jackets, four to eight fold expansion, surface condenser, and flue and return tubular boilers. The engines develop 250 indicated horse-power, with the consumption of 300 lb. of anthracite coal per hour; the efficiency being one horse-power per hour per 1.2 lb. coal. With the above indicated development of power and consumption of coal, she runs full 11 miles per hour in calm weather, as has been proved by repeated trials. In a winter cruise lasting 23 days (steaming time), with the wind varying from a full gale to a strong breeze, always in such directions that no sail could be carried, her average run per day was 200 miles, and the daily consumption four tons of anthracite. She is, however, capable of a much better performance. During the whole of the cruise the steam jackets were not used, but allowed to remain full of water, through a misapprehension of the engineers relating to steam traps.

It will be fair to assume that with the power required for a calm weather speed of 11 miles, her mean sea speed will be 9 miles per hour.

It is well known that for similar ships of different tonnage, the power required to propel them at given speeds, below the wave speed of the shortest ship, varies as the squares of the cube roots of the tonnages, and that for different speeds of the same ship, below the wave speed, the power required varies as the cubes of the speeds. These principles enable us to compare the Octavia's performance with that of large commercial steamships. Let us assume a ship of 5,000 tons displacement, having the characteristics of the Octavia, and compare the probable performance with that of the Pacific Mail S. S. Great Republic.

The last named ship sailed from San Francisco September 3d, 1867, and arrived at Hong Kong October 5th, the distance run being 6,623 miles by observations, the running time 691 hours, and the consumption 1,373 tons of coal, making the mean speed 9.586 miles per hour, and the consumption 4,451 lb. in the same time. For a similar speed of 9.586 miles per hour, the 5,000 ton ship will require only 1,848 lb. of coal per hour, which is a trifle more than 0.4 the consumption of the Great Republic for an equal speed.

Were the Great Republic as economical a ship as the Octavia, she would make the trans-Pacific voyage in the same time as now, and consume but 824 tons of coal, saving 549 tons, and adding so much to freight capacity. If the engine power of the 5,000 ton ship were so much increased as to make the consumption per hour equal to that of the Great Republic, the speed would be 12.9 miles per hour, the voyage be performed in $531\frac{1}{2}$ hours, saving $177\frac{1}{2}$ hours time and 352 tons of coal, adding so much to freight capacity. If the engine power were further increased so that the consumption per mile would equal that of the Great Republic, the speed would be 15.38 miles per hour, the consumption for the same time 7,143 lb., and the voyage made in 431 hours, saving 260 hours time.

LOCOMOTIVES FOR LONG RUNS.

Compiled from "The Engineer."

Express trains between important centers must be "through" trains in order that they may be worked with the greatest economy at the highest speed. This condition is not invariably easy of fulfilment; and until the invention of the water trough and scoop, by Mr. Ramsbottom, they probably could not have been fulfilled at all. At this time it is certain that the advantages to be derived from long, continuous runs are not fully realized; and it is more than probable that important changes in the method of working express traffic will be introduced before many years have elapsed. The London and North-Western Railway Company were among the first to perceive the advantages to be gained by traversing distances of seventy or eighty miles without a stop, and Mr. Ramsbottom placed at the disposal of his directors the means of traversing even greater distances without interruption.

The full advantage of the water trough system was not taken, however, until the completion of the great Runcorn bridge; and the novel announcement that Liverpool is to be placed within four hours of London by express train was reserved for 1869. Liverpool is in round numbers 200 miles from London, *viâ* Runcorn, and in order that it may be reached at 4 P.M. by a train leaving London at 12 noon, it is necessary that an average speed of fifty miles per hour should be maintained the whole way. To accomplish such a feat will be no mean achievement; its regular daily performance will be a novelty in railway engineering, and it is worth while to consider what has to be done, and by what manner of engines the work can be best performed. It is obvious that the run from London to Liverpool must be continuous. Each stoppage would consume at least three minutes during which the train would be standing; while an equal time would be expended in the retardation and acceleration of the train.

Whether an engine shall stop or not obviously depends on two things; first, its powers of carrying or taking in water and coal; and, secondly, its capacity for continuous exertion without examination or adjustment of parts. The largest tenders yet made hold little more than 2,000 gallons of water, while, with their frames and wheels, they represent each a load of over twenty-two tons. But the supply of water which these tenders carry would not last for more than a third of the distance to be traversed. Therefore their tanks will be replenished *en route* by the aid of scoops. It is not probable that these express trains will ever be of great length; exclusive of engine and tender they are not likely to weigh much more than seventy tons. The engine we may set down at twenty-eight tons, making a gross load of, say, 100 tons. The addition of a tender increases the whole load moved by say one-fifth, or the load to be drawn by the engine by two-sevenths. At 50 miles per hour the resistance of the tender will average about 25 lb. per ton, or 500 lb. for twenty tons; and, in overcoming this resistance, the engine must do work each hour equivalent to 132,000,000 foot-pounds. And in four hours, that is to say, on the entire run, the duty will amount to 528,000,000 of foot-pounds. Stated differently, more than 66 horse power indicated, will be expended by the engine in hauling the tender alone. As the water is consumed the resistance will be reduced a little; but, all things considered, we are disposed to think that we have under, rather than over, rated the amount of power which will be required to propel a 2,000-gallon tender at 50 miles per hour. Arrived at this point, the first question which suggests itself is, naturally: Is it possible to dispense with the tender? To this our answer must be in the affirmative. Seeing that we cannot do without water troughs, why not have more of them, and replace the 2,000 gallon tender by a 400 gallon tank. It is absurd, practically, to abolish water cranes, and yet to retain an evil which was necessary only because nothing better than the water crane was known. By getting rid of the tender, more weight would be rendered available for adhesion, and all the working expenses would be materially reduced. We are not in a position to state accurately what the expense of additional water troughs would be; but the value of the suppressed tenders, and the economy effected by the suppression would go far to compensate for the extra expenditure.

Reasoning on the foregoing basis, we assume that the best engines for working the Liverpool express would be tank engines, carrying enough water to last them about fifteen miles. As the quantity of water taken in would be comparatively moderate, the troughs might be made much shorter than those now used to fill a large tender; and the scoop arrangements are susceptible of modifications and improvements which would render the work of filling a certainty, instead of depending on the attention of the driver or stoker.

As regards the other characteristics of the engines, it may be taken as proved that they must be large, powerful, and heavy machines. However well light locomotives may answer for moderate speeds and short runs, on the Liverpool trip they would be out of place. The work to be done is heavy, and the engines doing it must be not only well up to their work, but a good deal above it. Outside cylinder engines, on eight wheels, four being coupled as drivers, and four placed in an Adams' bogie in front, would probably answer very well.* The tank would be placed beneath the barrel of the boiler, and a coal-box might run at each side. The cylinders would be 18 in. by 24 in. stroke, and the wheels should not be less than 7 ft. in diameter. Boiler pressure 120 lb. at most, and we should prefer to give the cylinder another inch of diameter, and to reduce the pressure to 100 lb. It will be said that this is retrograde practice, but we know that steam of great pressure and high temperature is very injurious to packing, and even to the iron of the cylinder and valve faces, which it is not easy to lubricate prop-

* This looks very like an American locomotive.—Ed. *V. E. M.*

erly under the conditions, and it is by no means improbable that on long runs, during which no water can find its way to the cylinder, more trouble may be caused by high steam than it is worth—trouble which would not be encountered at all if the runs were short. All the working parts should be stronger than usual, and rubbing surfaces should have much larger dimensions than are commonly given to them.

While considering this portion of the subject it may be worth while to illustrate in a compact form the work which the Liverpool express engines must execute. The driving wheels being 7 ft. in diameter will make 240 revolutions per mile, or 48,000 revolutions in running from London to Liverpool. When traveling at fifty miles an hour, 7 ft. wheels will make 200 revolutions per minute. It will require good fitting and lubrication to enable a couple of shafts running in four bearings, each sustaining four tons, to make 48,000 revolutions without ceasing for a moment, at the rate of 200 per minute, without heating or cutting during the four hours which must elapse before they can receive any proper inspection or attention; and the same holds good of the big ends of the connecting rods, the eccentrics and straps, etc. Each piston will pass through a distance of 192,000 feet, or nearly 36½ miles, in the course of the trip, and the contents of each stuffing box will be at the end of the journey as though a rod of iron 36½ miles long had been drawn through at the rate of 800 feet per minute. We say nothing of the concussive strains due to the speed. It will be seen that the conditions are severer, however, than those under which locomotives constantly work with great success, save in one important respect. When engines stop to take in water, an opportunity is afforded for at least a cursory examination, which an experienced driver is prompt to avail himself of; and it is possible to attend to a hot bearing or to fill up an exhausted lubricator. But the continuous exertion of nearly the maximum power of a large locomotive for a period of four hours is a condition which has never yet obtained in regular railway practice. We have no doubt whatever that the difficulties which may arise will be easily overcome; but we think it highly probable that it will be found expedient to design locomotives for this kind of service which will differ in not a few respects from those types of express engines now regarded as the best possible.

EXPERIMENTS WITH THE RODMAN GUN IN ENGLAND.

The 15-inch Rodman Gun, which some time since gave the British authorities a new idea of American ordnance, has again been fired—at a 20-in. target—with rather destructive effects upon the armor. The result is considered highly satisfactory as establishing the superiority of *English shot!* The "Mechanic's Magazine" gives the following account of the trial:

The gun was laid against the Plymouth casemate at 200 yards range. The powder charge was 83¼ lb. of large grain powder, and the three shots fired weighed 457 lb., 451 lb., and 450 lb. respectively. The new shot are spherical, and are made from a mixture of cast and refined iron at the Woolwich Laboratory, upon the method patented by Dr. D. S. Price, the original material having been first proposed by him to the Iron Plate Committee of 1862, both for projectiles and guns. The three rounds fired were highly interesting, as proving that round shot for large smooth-bore guns can be made in England of superior quality to the American shot. They, moreover, possess this advantage, that whilst the American shot are all turned true by machinery, these shots are cast in moulds with such exactitude as to be ready for use without any such subsequent mechanical operation. The three Price's shots fired on the present occasion were true to the 1-300th of an inch, and passed through the gauging rings both ways with exactitude.

The first round with the 457 lb. shot struck the 20-inch thick portion of the Plymouth casemate, making an indent 15½ in. across, and 5 in. deep, the indent, being saucer-shaped, with very steep rounded sides 9 in. below the indent was a curved crack, 2 ft. 4 in. in length; and, above it, a crack extended diagonally 9 in. to an empty bolt-hole, and thence beyond to the upper proper left corner of the lower portion of the plate. From the above bolt-hole, another crack ran off at right angles to the first. A large triangular piece of the covering plate, measuring 3 ft. 8 in. by 11 in. by 16 in., was carried away. The head of a 3-in. through bolt was also broken off, whilst behind the plate the 5-in. face plate of the proper 15-in. thick structure of the casemate was indented and buckled. At the rear of the casemate, the vertical buttress on the left proper of the port was bent; another vertical buttress 2 ft.

to the left was also bent. The second round was with the 451 lb. shot, which struck the 15 in. portion near the port-hole. More than half the shot remained fixed in the plate, plugging the indent, the centre of which was 3 ft. 11 in. from the granite base, the upper circumference of the shot being only 2 in. away from the upper edge of the plate. The metal here was split through, but there was no other fissure in the plate in direct connection with the shot-hole. Cracks extended in various directions, and at the rear considerable damage was done. The 450 lb. shot, in the third round, took effect on the upper portion of the proper left wing of the casemate, where it was 20 in. thick. It brought down two large pieces of the plate, which had been battered in previous experiments. The centre of the indent was 16 in. from the proper right edge of the covering plate, adjoining and in line with the upper part of the port, the shot-hole being plugged by more than half the shot, which remained in it. At the rear, the vertical buttress on the left of the port-hole was bulged and otherwise slightly damaged.

The striking velocities of the shot were as follows :—Round one, 1,360 ft. per second ; round two, 1,370 ft. ; and round three, 1,383 ft. The general effects upon the Plymouth casemate structure were very remarkable, in the flaking away of the thick face and covering plates, and in the bursting out of large portions of the rear planks and vertical struts. The first action of impact upon the front plates was to block out squarish areas by the extension of the old fissures of former rifle-shot wounds ; then the effect of the vibration of the layers of iron plates and planks against each other was to cast these blocked-out spaces to the front, a peeling action tending to the rapid distintegration of the iron wall. The results were highly satisfactory in establishing the valuable character of the metal of which the shotwere composed.

State Room Cars.—Much has been done for the comfort of night travelers, especially on our through lines to the West, and in the West. Only one of our roads—the Hudson River—is running upon every important day passenger train, a thoroughly luxurious car with really comfortable *arm-chairs*, as well as large and small compartments for private parties. This American type of first-class car has many advantages over the English type coming into use about New England.

New Works of the Chicago, Rock Island and Pacific Railroad.—These works are described in great detail in the Chicago "Railway Review." They are situated outside the southern limits of Chicago. The arrangement of the buildings is especially designed to save labor in handling material. They are built of brick with iron roofs. The machine shop is 336 ×112 ft., and 18 ft. high, with a wing 36× 50. One end is two stories high, with offices and drawing-room above, and offices, store-rooms, and tool-room, below. A longitudinal track runs through the middle, on one side of which are fifteen transverse tracks with drop tables; they are connected by a transfer table outside. The other side of the building is filled with Bement and Dougherty's tools, including three five-ton cranes, a double and a single wheel lathe, four radial drills, a quartering machine, an axle lathe, a 90 in. boring machine, a wheel boring machine, slotting, shaping and drilling machines, and lathes and planers in abundance. The boiler and smith shop is 344×80 ft.; the boiler end being 92 ft. long. It has a central railway track, and is provided with all the necessary tools. The smith shop has 36 fires and two steam hammers of 1,000 and 1,500 lb. each, and a scrap furnace. The Round House has an entire diameter of 278 ft.; the diameter of its inside space (turn-table in center, 23 ft. in diameter), is 158 ft.; the house part (roof pitching both ways), 60 ft.; containing 40 stalls; pits 40 ft. long; 12 ft. wide on the inner circle, from center to center of pier. The car shop is 252×80 ft., and 20 ft. high, in two stories, with a wing 200×80 ft. A foundry 130×60, with two wings 30×30 ft. is projected.

The entire cost of the works, thus far, is $550,000. The master mechanic is Mr. T. L. Twombly. The master car builder is Mr. J. L. Fogg.

The Ellershausen Process.—We have a very complete account of the rolling mill results of converting several kinds of iron by this process. Analyses are now being made, of the pig irons, ores, tap-cinders and puddle-bars. When they are completed, we shall publish the whole. The general result is a large loss of ore as compared with puddling, but an improvement of the iron, especially of a cold-short iron made from hematite ores, when treated with magnetic ores.

IRON AND STEEL NOTES.

Mining Produce of the World in Approximate Figures, expressed in German Cwts. By Prof. Tunner.

From the "Scientific American."

James Russell and Sons Works, Wednesbury.—This extensive establishment is one of the oldest in Great Britain for the manufacture of gas, locomotive and other tubes. The concern dates back, indeed, to 1816; and Russell's first tube patent was taken out in 1824. A portion of the works is occupied in the manufacture of taper tubes, for telegraph posts in India. It has been found impracticable to use wood, as the insects destroy it rapidly. By means of novel and ingenious machinery, the taper tubes can be turned out as readily as if they weie of uniform diameter. A large quantity of small tubing is manufactured for bedstead stuff, and is consumed in the neighboring district. These tubes are cut into lengths, and are polished by being placed in a rotating cylinder for a length of time. The pieces of strip to be made into tubes are first subjected to the action of a bending machine (a crocodile, as it is not inaptly termed), and in this way they are roughly shaped. They are then put into a Siemens heating furnace, and when a welding temperature has been obtained, the iron is drawn through the proper molding apparatus, and becomes a perfectly welded tube. The hot tubes are next passed under huge slabs, and are speedily straightened. In this department there are seven Siemens furnaces in operation.

The boilers in these works are constructed entirely of tubes, secured together by a junction that allows of the removal of single tubes in a most expeditious manner. The water is forced through the system of tubes, and is thus made to pass over the fire 26 times. The whole arrangement is cased in a plate-iron chamber. It is impossible that any serious accident can happen from explosion with this multitubular boiler; for if a tube burst it is a matter of only trifling inconvenience, and the defect can be remedied in an hour. The boiler will evaporate 6 to 9 lb. of water with 1 lb. of small coal. This class of boiler only requires to be more generally known to be more extensively adopted, especially in confined situations, where an explosion would produce the most disastrous effects.

Another department of the works is devoted to the mannfacture of spiral coils for tuyeres, &c., and of connections of various kinds. A considerable area is occupied with furnaces for the manufacture of lapwelded locomotive tubes, which is a branch of the trade specially developed by this firm. There is nothing peculiar in the manipulation of these pipes, though, of course, more care is required in the manufacture, and a higher quality of strip is required. The pipes, when made, are all tested by steam and hydraulic pressure. The foundry department includes the manufacture of all kinds of brass cocks, taps and fittings required in connection with tubes. The screwing shops are necessarily very extensive, and here the latest improvements have been introduced for performing the operations in the most expeditious and economical manner. The double screw-machines are patented by the manager, and are a great advance upon the methods usually adopted. In connection with the welding of boiler tubes we ought to mention a double furnace that is in successful operation, the grate being so arranged that two sets of tubes can be heated and worked at the same time from the opposite ends of the furnace. The longest tube made in these works is 34 ft. 1 in.; the largest is 15 in. in diameter. The larger sizes of tubes are in some cases used for curious purposes, one application being for ordinary gate posts. The heaviest tubes made weigh as much as from 16 to 17 cwt. each. The extent of the operations carried on by this firm may be estimated from the fact that about 140 tons of finished iron are used up per week, and that the total length of tubing turned out per annum averages from six to eight million lineal feet. The works cover an extent of nearly four acres, and the number of people employed generally averages about 400. A short time ago the firm passed into the hands of a limited company, though the management remains substantially what it was previously. Mr. Joseph Smith is the general manager of the concern, and Mr. Lambton Brown the practical manager.—*Mining Journal.*

A Novelty in Blast-Furnace and Cupola Practice.—Messrs. L. Sibert, D. C. E. Brady, of Buffalo Forge, and J. D. Imboden and S. M. Barton, of Richmond, Virginia, U. S., have patented a new method of treating iron ores while in process of reduction in a blast-furnace, and of treating cast-iron in a cupola or other melting furnace for the production of steel or a superior quality of iron. It also relates to a method of treating the molten metal after it has left the blast or melting furnace, but while it is retained in a molten state, for the purpose of effecting a more complete purification. The first part of the invention relating to the treatment of the ore or iron in the reducing or melting furnace consists in the use of a flux composed of manganese and common salt with limestone or shells, such flux being introduced into the furnace to or with the ore or iron, and acting upon the ore or iron during and after its fusion and while subjected to the action of the blast to decarbonise it, and to cause the expulsion and carrying off of silicon, sulphur, phosphorus, and other impurities, and bring the iron to such a state that on its being simply cast into moulds it will have the character of cast-steel, and may be used for various purposes without further manipulation, or may be subjected to hammering and rolling to reduce it to bars for the manufacture of tools or other articles requiring hardness and temper.* The method of introducing the flux to the furnace may be the same as that of introducing any other flux, but in order to prevent the salt from sinking too rapidly through the furnace it is proposed generally to reduce it by water to a saturated solution, and to throw or sprinkle this solution upon the ore or pig or cast-iron, and allow or cause its water to evaporate before introducing the ore or metal to the furnace.† The fuel and ore or metal may then be introduced to the furnace in the usual manner, and the requisite quantities of manganese and limestone or shells introduced above each charge of ore, and the operation of reducing or melting be proceeded with in the usual manner. The quantity of the flux employed may be varied according to the quality of the ore or iron to be treated. In aid of the manganese, and to some extent as a substitute for it, there may be used iron ores of qualities containing large proportions of oxygen, and by such use of such ores or of crude metal more or less highly carbonised the fused mass may be operated upon to regulate and grade the quality of the metal produced. When the steel or refined iron thus produced is to be made by hammering or rolling, or both, into bars of suitable shape for the manufacture of tools or other articles, it may be run from the reducing or melting furnace into heated ingot moulds of cast-iron, and then covered with powdered manganese, and the moulds set in a heating furnace and kept at a uniform high heat, but not in a molten state, for several hours, or until the metal has parted with a portion of its carbon which is taken up by the oxygen in the manganese, and has become of a more steel-like character. The metal having been thus kept at a uniform high temperature for a long time is cooled slowly in the furnace, and in the process of crystallisation under these conditions the molecules arrange themselves in such relation that the metal after hammering and rolling possesses the flexibility and tenactity of cast-steel. When it is desired to give the metal a higher quality, resembling that of the better qualities of cast-steel, instead of running it from the reducing or melting furnace into ingot moulds as hereinbefore described, it is run into crucibles which are placed in a heating furnace, wherein it is kept in a molten state for several hours before casting into bars or ingots, or other forms, and about from 20 to 30 minutes before casting, there is introduced and stirred into it sulphate of magnesia in the proportion of about one part by weight to every 1000 parts of the metal.—*Mining Journal.*

* Fluxing with manganese and salt is not new, but the production of tool steel ingots from the blast-furnace by means of such fluxes would be a novelty indeed.—Ed. *V. N's Mag.*

† See Van Nostrand's Magazine, No. 2, page 142.

The Lurmann Improvement in Blast Furnaces.—The use of Lurmann's improved blast furnaces, with closed fronts, (introduced into this country by Mr. Asmus) is making rapid progress on both sides of the Atlantic. In Germany it finds universal adoption. Very satisfactory reports have been received from a number of charcoal, anthracite and coke furnaces in the United States. The claims of the inventor, seem in most cases to have been more than realized. The weekly production is increased fifteen per cent. and upwards ; while that which was formerly considered the most arduous portion of the labor at the furnaces is entirely abolished.

Among the establishments at which this patent cinder-block is now in operation, we may mention the Thomas Iron Works, Hockendouqua, Pa. ; Shoneberger, Blair & Co., Pittsburg ; Brady's Bend Iron Co., Pa. ; Carbon Iron Co., Parryville, Pa. ; Northampton Iron Co., Bethlehem, Pa. ; Sligo Furnace, Pa. (charcoal) ; Pennsylvania Furnace (charcoal) ; Muirkirk Furnace, Md., (charcoal) ; Cleveland Rolling Mill Co. ; Chicago Iron Co. ; and New Jersey Zinc Co., Newark, N. J.

In a few cases, the introduction of the new improvement has not been attended with satisfactory results ; but superintendents and workmen will hardly be able, in view of its universal success, to satisfy their employers that the fault is in the principle of the invention itself. It is not surprising that prejudice and private interests should in many cases delay the introduction of really beneficial improvements ; and on failure arising from such causes, we shall waste no words at present. We think it well, however, to warn American iron-masters against one of their own besetting sins, which, in the present instance, may lead to unnecessary disappointment.

In trying an invention like Lurmann's cinder-block, which has been already endorsed by experience, an iron-master, who is not yet familiar with it should follow strictly the directions of the inventor. One of the great difficulties with which this improvement has had to contend has been the itching desire of American metallurgists to vary it *before they had tried it.* Many are afraid that the cinder will not run through a hole so small as the drawings prescribe ; and they at once increase the bore of the cinder discharge, thereby materially lessening the advantages which it secures, by necesssitating a periodical stoppage of the blast. One inch and a half at the narrowest part is large enough diameter of cinder-discharge for the largest anthracite furnace. If these dimensions are exceeded, the blast soon follows the cinder with such force, that it must be turned off or slackened to allow the opening to be closed. We do not insist upon a continuous discharge of cinder, though Lurmann himself has obtained in this way the best results ; but we think both fairness and prudence should lead our furnace men to adhere to the proportions and constructions he proposes, until they have used them long enough to be certain they can better them.—*American Journal of Mining.*

Manufacture of Iron and Steel—new Processes.—Messrs. A. Ponsard and F. E. Boyenval, of Paris, have patented a peculiar process and furnace for manufacturing cast and wrought iron and steel whereby the costly blast-furnaces hitherto employed are dispensed with. The furnace is constructed similar to a reverberatory furnace, with a double sloping hearth for the collection of the molten metal. The hearth is heated either by an ordinary furnace, or by gas. Upon each of the sloping sides of the hearth rest the lower ends of a number of vertical fire-clay tubes or crucibles, without bottoms, such tubes entering at their upper ends with holes in the roof of the furnace, which roof is covered by a cast-iron plate, forming a platform, and being provided with moveable lids which fit over the mouths of the different springs leading down into the tubes. The ore, fluxes, and fuel are fed into the several tubes from the platform ; the flames circulating round the exteriors of the tubes effect the fusion of the ore without coming into contact therewith, the small amount of fuel contained inside the tubes along with the ore and flux, in order to effect the deoxidation of the ore and the carburation of the metal, should be of the best quality. It will thus be seen that two distinct kinds of fuel are employed—the ordinary fuel, for the purpose of fusion, and a superior fuel, of which only a small proportion is required. The molten cast-iron runs out of the bottoms of the vertical tubes and down the sloping sides of the hearth, and as fast as the contents of the tubes subside or descend fresh supplies of ore, fuel, and flux are added, thus rendering the process continuous. The molten metal is run off through a tapping hole in the side of the furnace, and the slag is removed through a separate opening from time to time as required.

In making wrought-iron the same apparatus is employed, and the wrought-iron is obtained direct from the ore. The ore employed should be first reduced to a metallic state, by subjecting it to an elevated temperature in a furnace in contact with the fuel. The ore thus reduced is introduced into the vertical fire-clay tubes, and the process continued as for the production of cast-iron, taking care, however, that no coal be mixed with the ore, which would in such case become carburated, the result being cast-iron or steel. In making steel the process is substantially the same as for cast or wrought-iron.—*Mining Journal.*

Production of large Homogeneous Masses of Wrought-Iron.—Some years since, the welding of two or more puddled balls into one, under a steam hammer, was practised in Wales, and, by this means, large masses were produced, but the process was not satisfactory, because the surfaces of the balls became oxidized, and good union could not always be secured between them in consequence. Puddled balls are now welded in the same way, both at Consett Iron Works, Durham, and on the continent of Europe, but the process is, in both cases, open to the objection we have just pointed out. Now, by welding the puddled balls together *in a furnace,* according to the invention of Mr. John Harris, of the Harefield Iron Works, Middlesex, and Mr. Vaughan Pendred, of London, (Editor of "the Engineer,") a perfect union is secured, because the iron at the time of welding is surrounded by a deoxidizing or neutral flame, caused to be present in the forging hearth by regulating the damper. The formation of scale is thus effectually prevented on the faces to be united ; the iron or steel, too, being maintained at a high temperature, the cinder or slag is kept fluid or lively, and may be the better expelled. Another advantage is that the cost of producing rails, armour-plates, etc., will thus be much reduced, because a mass of homogeneous iron or steel may be made at once of sufficient size to form a rail, armour-plate, or shaft, and the process of reheating, cutting, and piling, may, therefore, be dispensed with.

The machinery for effecting the process is fully illustrated in the "Mechanic's Magazine" of Feb. 26, 1869. Two horizontal steam hammers on opposite sides of a heating furnace, strike, through suitable openings, upon the masses within the furnace. A similar process for building up great guns was devised by Alonzo Hitchcock, an American Engineer, during the late war, and is illustrated on page 386 of "Ordnance and Armor." Gas welding in its various applications is considered by experts to be one of the most promising directions of improvement in iron construction. The results of Bertram's gas welding of boilers and girders is well known.

Curing Bad and Burned Steel.—A locksmith of Mulhouse, named Herrenschmidt, claims to have discovered a mixture which is said to give to the commonest steel the grain and the temper of the finest cast metal, and, moreover, to have the power of bringing back the original quality of steel which has been burnt. The mixture is composed as follows : With 16 litres of distilled water mix one kilogramme of hydrochloric acid, 19 grammes of nitric acid at 36 deg., 21 grammes of sulphate of zinc, and 100 grammes of tripoli. In this mixture is to be placed a piece of cast iron of the first fusion, weighing 100 grammes; when the acid mixture has acted on the iron for 24 hours, the composition is ready for use in the ordinary way, and it remains effective till it is all used.

Bessemer Steel in France.—The production of Bessemer steel last year in France was 42,601 tons; in this total rails figured for 25,760 tons.

Applying Hydrocarbons for Smelting.—The improvements in the use of hydrocarbonaceous fluids in combination with super-heated steam for the purpose of smelting, working of metals, etc., provisionally specified by Mr. Paul Rapsey Hodge, of London consist in the use of compound jets, wherein the steam and hydrocarbons are brought together at the same time in their proper equivalents to produce proper combustion. If for smelting or melting purposes for any of the metals, he inserts a compound jet in combination with, or in close proximity to, the tuyere holes or blast, so that the flame and heat arising from the combination of these two elements may unite and commingle with the other combustibles of the cupola, and reduce the "charge." He further proposes the use of these compound jets in the smelting, melting refining, or annealing of iron, brass, copper, lead, tin, silver, gold, ro any other metal, either in the cupola, reverberatory, or annealing furnace, or in furnaces wherein the metals are reduced or melted in pots. He uses the compound jets of hydrocarbon and steam in the heating and re-heating of metals for forging, welding, or brazing, as in the manufacture of iron or brass tubes, and by distributing these jets at such distances as will emit their flame to produce a uniform heat throughout the whole length of the furnace, such jets to be used either in combination with or without any other fuel. The compound jets are also applicable for the calcination of metalliferous ores, and for other purposes.—*Mining Journal.*

Utilizing Old Steel Rails and Rail Ends.—Mr. J. Thompson, of Stafford, England, has lately patented two improvements in this direction, both of which, however, have been previously practised in this country. His process is first, by dividing the rail, that is to say, passing it between rolls, so turned and arranged that they present V shaped projections to the heated metal passed between them, which has the effect of dividing the mass into many parts, which are afterwards rolled down into bars, &c. And, secondly, his improvements consist in so arranging his rolls that the thinner portions, such as the intermediate part of the top and bottom of a rail, shall be supported while the larger portions are reduced Thus by a series of rolls or grooves, a rail end may be first reduced to a flat mass, and then compressed or rolled edgeway, so that the middle portion shall be wrought and be subjected to the beneficial effects imparted by the processes, until the whole mass is reduced down to a bar of a suitable or desired form in its transverse section. In no case is the metal, while under operation, allowed to overlap, an effect he entirely avoids, as the description of metal named will not weld like ordinary iron or steel.

The Flexion of Iron and Steel.—The results of all the experiments on flexion are thus briefly summed up by Mr. Styffe, in his new work (reviewed on another page) on iron and steel:

1. Iron sustains at low temperatures a greater and at high temperatures a smaller load than at the ordinary temperature, before it obtains any perceptible permanent deflection.

2. The modulus of elasticity for steel and iron on flexion may, for practical purposes and without committing any considerable error, be generally assumed equal to that on traction. It is diminished by permanent deflection, but may be restored by heating, especially if raised to a red heat.

3. By hardening steel, its modulus of elasticity is diminished; but this diminution has not, in any of the hardened bars examined, amounted to more than about three per cent.

4. The elastic force of steel and iron on flexion, as on traction, is increased on reduction of temperature and diminished on elevation of temperature. The amount of this increase or decrease for a change of temperature equal to 1.8 deg. Fah. (1 deg. Cent.) does not, however, in general amount to more than 0.03 per cent, and apparently never rises to 0.05 per cent.

The Bessemer Steel Trade.—It is understood that Mr. Bessemer has signified his willingness to reduce his royalties from £2 to 2s. 6d. per ton, except for steel rails, for which a rebate of 20s. per ton is already allowed. Ordinary Bessemer steel will thus be reduced nearly £2 per ton, and rails about £1 10s. This will remove all inducements which might otherwise exist to infringe the patent-rights remaining to Mr. Bessemer after the expiry of his principal patents in the course of next year, and at the same time will give an impetus to the steel rail trade, by permitting the steel rails to be sold in the market at a price but little higher than that of iron. If the Heaton process should solve the question of converting *cheap* pig iron into steel, iron rails may, probably, be entirely displaced.—*Mining Journal.*

ORDNANCE AND NAVAL NOTES.

Comparison between Polygonal and Studded Projectiles.—Under the above heading we have a very suggestive paper from the pen of Mr. Joseph Whitworth. In this paper Whitworth projectiles cast with rifled polygonal surfaces are compared with Woolwich projectiles, with dove-tailed recesses for the insertion of soft metal studs to give rotation. The subject is treated under three heads.

1. *Simplicity and Economy of Production*—Polygonal.—Projectiles for field guns are fired as they are cast, just as in the case of smooth bores. For large guns, they are planed or shaped, one machine only being required. The time occupied in rifling a 9-inch shell, weighing 300 lb., is only twelve minutes. In studded projectiles the body of the shot has to be cast with recesses for the studs, or they have to be drilled in, and recessed with cutters. In either case these recesses are a source of weakness, rendering the shell liable to break up in the bore of the gun. The 9-inch projectile has 12 studs inserted in it, by pressure, each one requiring attention; there are also six different surfaces to attend to, viz: The body of the shot, the outer circumferences of the studs, the right and left sides of the rear studs, and the right and left sides of the front studs, which are made narrower than the rear studs, on account of the increasing pitch. The projectile for field guns has six brass studs fitted into it.

Studded projectiles have in their manufacture to pass through several workmen's hands, and costly machines have to be employed, viz: lathes or grinding machines, drilling and punching machines, in addition to the rifling machines. The cost of wages for the large projectiles is many times greater than for those of the polygonal system; the cost of the metal for studs is also considerable; and to this must be added the cost of a packing case or thick canvass bag for each projectile, on account of the soft metal studs being liable to injury if one projectile is allowed to rest upon or knock against another. In the penetration of armour plates the studs are an obstruction, and the power required to shear them off is so much deducted from the force of the projectile.

2. *Area of Bearing Surfaces.*—For a 9-inch polygonal projectile, the rifled surfaces which both support and rotate the shot have an area of 187 in. The 12 studs of a 9-inch Palliser projectile have a circumferential area of 18 in. for supporting the shot, but the area of the sides of the six rear studs, by which the rotary motion is given, is only 1-6 in. No practical engineer would think of providing so small a surface to give even a small amount of rotation to a body weighing 250 lb., much less when the rotation of the shot at the muzzle of the gun has to be at the rate of about 2,400 revolutions per minute. The increasing pitch which has been adopted prevents the use of more than one stud in each groove for giving rotation. This varying curve is the worst possible mode of imparting rotation, for each rear stud can only bear against the side of the groove of the gun on a line of its surface, on account of the ever varying curve, except by excessive pressure, which jams and distorts the soft metal, and occasions liability to accident. The greater the amount of windage, the greater will be the liability to accident.

3. *Centring of the Shot in the Bore.*—In starting, the polygonal projectile centres itself, so that its axis coincides with the axis of the gun, and it is propelled through the bore with a steady equable motion. The studded projectile in starting does not rise and centre itself parallel with the axis of the bore, but lies on the bottom; consequently, the gases and unconsumed powder pass over the projectile, causing excessive scoring, and tending to keep the shot down, thus giving increased pressure to the outer surfaces of the studs, particularly those of the rear, and adding to the irregular and vibratory motion as it is propelled through the bore, and the greater the windage, the more unsteady will be the motion.

Field Artillery.—With respect to field artillery, but few important changes occurred in the course of last year. For the most part the systems adopted have merely been developed and carried out. England alone has adopted a new plan by abandoning the breech-loading Armstrongs for the muzzle-loading seven, eight and nine-pounders of Whitsworth. The smooth-bore has been almost universally abandoned except by America, which retains smooth-bore twelve-pounders, and perhaps by Spain. Northern and Southern Germany have the same system and caliber breech-loading four and six-pounders. Belgium most closely resembles them in this respect. Revolving cannon, mitrailleuses, and other similar instruments have been almost universally experimented upon, with excellent results as far as short and middle distances are concerned. Great value is attributed to them in the defence of defiles and trenches, but they have been nowhere adopted except in France, where they are to be used in the field. With regard to heavy artillery, the chief interest is excited by the question of iron plating. After the English experiments it may be considered as certain that the smooth-bore used in America, in spite of any possible increase of caliber, is inferior to the rifle-bore in its effect on such armour. The English experiments on plated land fortresses were highly interesting, as they show that, under favorable circumstances, twelve-pounders are equal to attacking the strongest plating. At present the sides of ships covered with eight or nine inch plates, like those of the English Hercules, are no protection against the heavy artillery now on trial. While the English tubes are formed of wrought iron, France and Sweden use cast iron, and Prussia, Russia and Belgium, cast steel. As material for projectiles use is made of cast steel and hard cast iron prepared in England by Palliser, and in Germany by Gruson. That cast in Germany most closely approaches cast steel, as the balls made of it penetrate the plating without being broken, as those of Palliser are. The chief advantage of hard cast iron is its great cheapness when compared with steel. An important problem with respect to siege trains, and those intended for the defence of fortifications, is the placing of the guns behind earthworks, so that the men that serve them may be covered without the range being obstructed or narrowed. The Prussian system is inferior to the English one in this respect, but Mr. Moncrief attains his end by means of a complex mechanical arrangement, and at a far greater expense. The prismatic powder is now much used for heavy artillery. In conclusion, attention is called to the fact that, in spite of all activity and all endeavors after perfection, we are still far from having brought the matter to a definite conclusion. It is true that time and circumstance often force us to make a choice, but we have not yet attained a point from which the end can be seen.—*Kreutz-Zeitung.*

The English Guns and Gun Factory.—Englishmen have reason to be proud of Woolwich as it now is, grumblingly as they may pay the bills which the great national arsenal involves. There is there that high order of engineering thought, engrafted upon Sir William Armstrong's best but not always useful thoughts, of which all Englishmen may congratulate themselves. There is the highest order of skill, perfected by the longer, steadier, more sober training, of which we may justly boast as a nation, when compared with other industrial nations. To see old cast iron guns puddled into good bars, to see them welded up to lengths of from 150 ft. to even 270 ft., to see these heated in a heating furnace 190 ft. long, with, in some cases, 80 ft. of the bar projecting beyond the rear end, to see these coiled on a coiling mandril, to see two or even three of these coils wound upon each other, to see these solidly welded into a single block, a block which, for the new 25 ton guns, weighs, in its rough state, upwards of 25 tons, all this is a sight to see. It is wonderful to a forgeman—to any worker in iron—to see these blocks brought out perfectly sound, turned in lathes weighing 84 tons, and swung bodily into other lathes, formed for turning the trunnions. It is something to see these guns reduced 7 in. in diameter at a single cut, something to see their steel tubes bored out of the solid, in segmental chips of $\frac{1}{8}$ in. feed, $5\frac{1}{2}$ in. radius, something to feel or to shrink from feeling the heat generated in boring, notwithstanding the stream of cold water so freely admitted; a stream almost large enough for the abundant supply of many a country village—all this is something, but it is much more to know, as we do know, that the guns thus made, costly although they may be, are indisputably the *best* guns for naval service known to ordnance engineers of the present century. —*Engineering.*

Armour *vs.* Speed.—"As it has proved impossible to invent a plating absolutely impervious to guns of a high caliber, some have lately begun to question the relative advantages of a defense, the value of which depends on distance. Hence many States have commenced building very swift vessels of wood, which are to be armed with heavy guns, and to carry a larger supply of coal instead of armour, and these may be very useful in conjunction with the iron-clads for the protection of the merchant navy, though they cannot supercede the latter in the line of battle, or the protection of the coasts. America has lately built the Wampanoag, a vessel of great speed, and England is now fitting up on similar principles the Inconstant, a frigate lately launched at Pembroke. In order to obtain great speed, the chief advantage proposed, Reed has given the frigate an exceedingly light and slender form. Two smaller vessels, the Volage and the Active, each of 2,322 tons burden and 600 horse-power, are now being built at the docks of Blackwall on similar principles. The Spartan, of 6 guns, lately launched at Deptford, is still smaller, and its superiority lies in the small quantity of coal consumed. The Sirius, a wooden corvette, which is intended to supply the place of those formerly in use in hot climates, is a vessel of six guns, 1,268 tons burden, and 350 nominal horse-power, constructed by Reed, and furnished with very healthy cabins and berths, and excellent ventilation. Even if these vessels should satisfy all the expectations formed of them, they would not, as we have already said, supercede the iron-clads, and Dupuys de Lôme in France, and Coles and Reed in England, rival each other in ingenious endeavors to perfect the construction of the latter."—*Staats Anzeiger.*

Resignation of M. Dupuy de Lôme — The French Navy.—In the French naval world the news of the day is the resignation of the Chief Constructor of the Fleet, M. Dupuy de Lôme, who has thrown up his office and gone to canvass a seaboard constituency. It is presumed that he could not get on with the present First Lord, Rigault de Genouilly. Most of the large wooden screw vessels, and all the iron-clads, with the exception of the Couronne and a few floating batteries built by Lemoine, were constructed by M. Dupuy de Lôme. The resignation is kept dark, as there is no naval architect to replace the engineer who applied steam to the navy when he built the Napoleon, and plates to frigates when he built La Gloire. The state of the French fleet for the present year is thus set down: Ships, 2; frigates, 19; corvettes, 9; coast-guards, 7; floating batteries, 26—total, 63 iron-clads. Of screws there are 241, or 15 ships, 10 frigates, 21 corvettes, 60 avisos, 70 gunboats, 35 transports and 2 specials. To this force must be added 51 paddle-wheelers and 100 sailing vessels. Of the iron-clads we may remark, that the two ships, the Magenta and Solferino, are not so large, and are by no means such formidable vessels as the largest type of frigate, represented by the Ocean, which is now ready for sea. M. Dupuy de Lôme designed five of these frigates before leaving office —the Friedland, Marengo and Suffren, laid down a couple of years ago, and the Richelieu hardly commenced. The Ocean will carry more guns than the Magenta, and she is more thickly plated; besides this, she has four fixed turrets on each corner of her central battery, each armed with an 11-inch gun. The Minister of Marine, when he defends his budget next week, will perhaps furnish some details respecting his department. — *Army and Navy Gazette.*

Details of the American Navy.—Mr. Ford, the Secretary of our Legation at Washington, in his report to the foreign office, dated 31st December last, states that the cost of the navy during the past year was £3,656,066, the total number of vessels of all sorts being 206. The following table shows its character:

	No.	Guns.
Ironclads	52	129
Screw steamers...........	95	938
Paddle-wheel ditto........	28	199
Sailing vessels...........	31	477
Total...............	206	1743

It will be seen that the American ironclads carry an average of only two and a quarter guns. The European squadron includes five vessels: the Asiatic, nine vessels; the North Atlantic, six vessels; the South Atlantic, five vessels; the North Pacific, eight vessels; and the South Pacific, six vessels. The net proceeds of the prizes captured during the late war had been adjudicated at the large amount of £3,151,720. The list of the officers shows a great absence of the ornamental class; it includes one admiral; one vice-admiral, and only ten rear-admirals. There are 302 engineers, 20 chaplains, 11 professors of mathematics, 5 naval constructors, 5 assistant-constructors, and 5 civil engineers. Mr. Ford states that the Secretary of the Navy calls attention to the fact that in none of the navy yards of the United States is there more than a single dry dock, and that there are but six in the whole country—a deficiency which would be seriously felt in the event of a maritime war. He adds that the docks at Cherbourg and Toulon, in France, and at Portsmouth, in Great Britain, each contain a greater number of dry docks than all the United States' dockyards combined; and that whilst Great Britain, France, and other maritime powers are increasing their dry dock facilities, nothing in a similar direction is being done in the United States.—*Engineer.*

Railway Education for Soldiers.—It is now proposed, though not for the first time, to teach the soldiers of France how to run a railway, in view of the new and important function of railways in warfare. Says a Paris correspondent of the "Engineer": The Minister of War and the Minister of Marines have applied to the great railway companies to arrange for the instruction of the military engineer corps in the work of laying down and keeping in order iron ways which may become necessary in case of war, and also in the stoking and managing of locomotives. The companies are said to have expressed their readiness to do all in their power to carry out such measures, considering that it would be greatly to their interest to have a body of disciplined and intelligent men instructed in such duties, and from which hereafter they may obtain engine drivers, stokers, and other servants and officers.

Moveable Harbor Obstructions.—A subject under consideration by the French naval authorities, is the defence of maritime ports without obstructing the way; several plans have been proposed in the case of Toulon, but none have been considered satisfactory, and a new project is now put forward, which consists in the establishment of a floating stockade, which can be laid across the entrance of the port or withdrawn in a few hours, and which at the same time shall be sufficiently strong to withstand the full force of a steam squadron, and thus guarantee the port from all chances of sudden attack. The problem is not a very easy one to solve, except at a considerable cost, and we shall see whether the military and civil engineers will hit upon a solution of it.—*Cor. Engineer.*

Italian Iron-Clads.—From a recent report of the Italian Navy Minister it appears that during the year 1868 three iron-clads were completed in the Italian dockyards. These vessels were the Venezia, a frigate; the Caracciolo, a corvette; and the Alfredo Cappellini, a gunboat. Their aggregate tonnage was 8,000, their steam power 1,270. Four other iron-clads were in course of construction at the end of the year 1868, and the works were being pushed forward with great activity. Italy is now building her war vessels in her own dockyards, and fitting them for sea without foreign assistance, except in the case of the guns, which are of the Armstrong pattern, and which have accordingly to be obtained from England.

Proof of U. S. Guns—Error Corrected.—In the last number of this Magazine, we copied an item from the "Philadelphia Inquirer" on the cost of heavy guns, in which it was stated that "from the spring of 1864, all 15-inch guns procured at Pittsburgh were taken without any powder proof, according to an order from the Chief of Ordnance." This statement, we now learn officially, is not correct. Every 15-inch gun, and indeed every gun procured by the ordnance department at Pittsburgh was subjected to the powder proof before being taken. And the Chief of Ordnance never accepted or authorized the removal of any guns from any one of the foundries before it was fired.

Soft Armour Plates.—The results obtained last summer on the trials of the "Millwall Shield" and "War Office Casement," as compared with the late results against the "Plymouth Fort" section, seem to have settled the question for ever as to the relative advantages of soft and hard iron plates for resisting shot. In the former trials the plates were soft and copper-like, and there was scarce a case of a crack, although the plates were hit much harder, while the result upon the hard plates of the Plymouth Fort were fearfully great, even against the twentieth portion of the target.—*Army and Navy Gazette.*

The Forty-Ton Gun.—Preparations are making at the Royal Gun factories for the manufacture of the 40-ton gun, some time ago designed by Mr. Fraser. Of the 25-ton 11 in. guns, a good number are already completed.

A New Rifle, the invention of Meyhöfer, in East Prussia, is said to be capable of discharging thirty shots a minute, and of killing at 1800 paces.

RAILWAY NOTES.

The First Locomotive.—Pen-y-darran, Wales, is chiefly remarkable for its connection with the first tramway—for which an act of Parliament was obtained in 1803 for the first locomotive ever tried,—and with the able inventor, Trevethick, who there made his first essay. The first run of the locomotive occurred in February, 1804. Previously there had been a whisper in the scientific world of the use of steam and of its employment in propelling vehicles, and abortive attempts having been frequent. Samuel Homfray by some means was brought into connection with Trevethick, and the result was that this able but ecentric man visited Merthyr, and in conjunction with a self-taught mechanic, one Rees Jones, whose homely portrait can be seen in the Kensington Museum, began to build his locomotive. Building is not an inappropriate word in this case, for the stack was actually built up of bricks the same as an ordinary chimney, and the whole affair was peculiarly odd. The stack was tall and clumsy, the body dwarfed, perched on a high framework, so as to approximate to the spider fashion; the cylinder, in addition, was upright; the piston worked downwards, and at every revolution of the wheels there was a monstrous clang produced which, heard nowadays with the asthmatic puffs of steam, would provoke the gravest mechanician to laughter. When completed, Homfray introduced his friend Richard Crawshay to the novelty, doubtless much to that individual's amusement, certainly to his incredulity as to its being fit for anything, for he readily accepted a wager with Homfray for £1,000, maintaining that it would not convey a load of iron from Pen-y-darran to the navigation—a distance of nine miles. The eventful day arrived for the trial, and never had there been so much excitement. The sturdy Englishmen were there, and natives from every Welsh county lined the road, and mounted every eminence that commanded the tramway; and when Trevethick jumped on his iron steed, and began slowly to move onwards amidst clanging iron and puffing steam, the uproar was terrific. By the arrangements made no one was allowed to assist the dauntless Cornishman and for a time he did not seem to want it. Surrounded by a host, he passed down the valley, making about five miles per hour when a sad misfortunate happened,—the clumsy stack came in contact with a bridge and was ruined! Trevethick stood for a moment among his bricks, but only a moment. Fertile in resource, he was soon steaming onward again, and not only conveyed his load of iron to the navigation, but a crowd of exultant passengers along with it, who to their latest day prided themselves on their glorious ride. It was fortunate for Homfray that the wager was a loose one. The iron was taken down and the bet won; but Trevethick failed to bring his empty trains back, and for some time the new invention as a mode of transport remained in abeyance.—*Engineer.*

WORKING EXPENSES OF BRITISH RAILWAYS.

Mr. Forbes, general manager of the London, Chatham and Dover railway, has furnished to the "Railway News" the following very complete comparative statement of working expenses on twelve of the principal railways of the United Kingdom, for the half-year ending December, 1868.

	LON., CHATHAM & DOVER.			SOUTH EASTERN.			LON., BRIGHTON & SOUTH COAST.			LON. & SOUTH WESTERN.			GREAT NORTHERN.			LON. & NORTH WESTERN.

GERMAN ASSOCIATION OF RAILWAY ENGINEERS.—Some years ago, all the German railway companies joined in a kind of association called "*die Techniker, Versanvurg des Vereins deutscher Eisenbahn Vervaltungen*," with the object of bringing the experience of their respective railways into use to their mutual benefit. A technical commission of about fifty members was selected from amongst the most eminent men from the different divisions of a railway administration. In 1865 a general meeting was held at Dresden, when it was decided that the long period of seven to eight years between each general meeting should be shortened to two years, and the next general meeting was fixed for 1867, but on account of the war did not take place till 1868—at Murich. Of the sixty-eight different railways belonging to the association, there were no less than fifty then represented, generally by the director-general and the chief engineer.

The advantage of these general meetings is, that the technical commission had brought together all the experience gained on the respective railways up to the present day, and answered all the questions which at the former meeting were proposed for discussion. Of the questions twenty-two related to the permanent way department, twenty-six to the engine and rolling stock, and fifteen to the traffic department. On all these questions each railway company had given their experience, and the technical commission had from these facts made a *résumé* in answer to each question and published a large volume with tables as a "referate," given to each member. At the general meeting each question was read, as well as the *résumé* in answer to it, and if no objections were made by any of the members it was passed, as decided upon by the general meeting.

At the meeting at Dresden again there were formed different sections to discuss the different questions where members of each of these branches could more thoroughly discuss the matter without unnecessarily occupying their fellow-workmen's time, as was the case, when all the questions were treated together. It is only just to the technical commission to acknowledge the great accuracy, care, and skill by which all the questions have been treated. Indeed, we are told that the commission had had thirty meetings to investigate all the statements from the railways, and draw from them a *résumé*.

THE PROGRESS OF THE NARROW GAUGE IN GREAT BRITAIN.—The Great Western Railway has always played a prominent part in the annals of British railways. Its career in connection with the broad gauge is one of considerable importance, and its struggles with powerful competitors in the interest of the narrow gauge will not soon be forgotten. It stretches its giant arms to Exeter and South Wales in one direction, and to Birmingham and Liverpool in another; and in spite of every obstacle, it presses the London and North Western hard, as the greatest British railway. But at a time when it has attanied an importance of which its early promoters never dreamt, even in their most sanguine moods, the Great Western appears to be abandoning its first love, and to be gradually likening itself to other British railways *by reducing its gauge to the width generally adopted.* The whole of what is known as the northern division of the Great Western has now become narrow gauge; and, although the broad gauge still stretches westward as far as Exeter and Truro, it is probably doomed for good and all, and *will disappear altogether as years roll on.* It is with railways as with individuals—a policy of eccentricity and isolation does not pay, and the railway which cannot send its trucks all over the empire, if need be, is sure to command but a feeble traffic; and to yield meagre dividends. —*London Colliery Guardian.*

BRITISH AND PRUSSIAN RAILWAY STATISTICS COMPARED.—The *Staats Anzeiger* contains a comparison of the railway traffic of Great Britain and that of all the provinces of Prussia for the year 1867, according to which there was one Prussian mile of railway to every 1.9 Prussian square mile in Great Britain, and for every 5.3 sq. miles in Prussia. The capital invested averaged 1,100,198 thalers per Prussian mile in the United Kingdom, and 549,975 thalers in Prussia. In the former State 2.8 locomotives and 90.16 carriages, and in the latter 2.4 locomotives and 122.6 carriages were employed for every mile of rail. In Great Britain 17,338 trains run daily; in Prussia only 6,586, but the distances traversed by the latter were far greater. In Great Britain 287,807,904, and in Prussia 38,766,866 persons were conveyed. In the former State the expenses amounted to 43,001 thalers, and the receipts to 86,480 thlrs., and in the latter to 43,091 and 78,813 thalers per mile. The expenses are as follows: In the United Kingdom, for management of the line, 19 per cent transport 62, general management 18.3; in Prussia they were 32.6, 61.4 and 6 per cent. The paid up capital averaged in Great Britain 3.91, and in the Prussian private lines 5.98 per cent.

THE PACIFIC RAILWAY.—Mr. Dilke, in "Great Britain," says: The discovery that it was practicable to carry a railway over the Rocky Mountains, within American territory, fell almost as heavy on the hopes of the Canadians as the discovery of the route by the Indies to the Cape lighted on the old prosperity of Venice. Of all the marvels of American energy, of all the triumphs of rough and ready engineering, the Pacific Railway is perhaps the most marvellous and most triumphant. They say the rails can be laid at the rate of nine yards in fifteen seconds, and the workmen have to cross their hands while the 300 or 400 tons of iron are brought up day by day to the front. The works are carried on in an enemy's country, and the advanced carriages of the construction train are well supplied with rifles hung from the roof.

THE CENTRAL RAIL SYSYEM.—An experiment has been made on the road between Roanne and Charlieu, with a modified kind of mountain railway; a pair of rails about a mile in length was laid down by the side of the road, following all its irregularities, a central rail being added in those parts where the gradients were unusually steep, and the engine provided with horizontal wheels, which nipped this central rail. The report of the trial is but meager; but it is asserted that the engine, to which were attached three ballast trucks, worked admirably, going up and down the inclines with ease, not only with the aid of the horizontal wheels, but by means of these alone, the ordinary driving wheels being thrown out of gear.

Railway Traveling in India.—A correspondent of the Times writing from Umballa says: "As a striking illustration of the changes being wrought by railways in India, it may be recorded that I traveled from Calcutta to Umballa in 41 hours, including stoppages, by the special train which preceded the Governor-General's, spent 24 hours there, and returned by the ordinary express train in 52 hours—a distance of 1154 miles, or 2308 both ways. The sleeping carriages enable the traveler to undertake such a continuous journey with comparatively little fatigue ; but the dust and dirt, who shall describe? The cost, first-class, is about £12 each way a servant. Dinner at refreshment-rooms, better than those of England, cost 6s. 3d., with a quart of Ind Coope and American ice *ad lib.*"

Safety Device for Car Axles.—A new device for preventing serious results from the brakeage of axles when in motion, has been lately applied on the Providence and Worcester Railway. When first applied, it consisted of a wrought iron sleeve surrounding the axle, and extending from wheel to wheel, the sleeve being applied in halves, and firmly clamped together and to the safety-beam of the truck-frame. Now, in addition to the sleeve, the rims of the wheels are capped over with strong iron shields, which are bolted to the safety-beam and to the frame of the truck at the side, and fore and aft, so that the wheels and axle are pretty securely caged.—*Cor. Railway Times.*

Wooden Wheels.—The directors of the New York and New Haven Railroad have decided to try an experiment in the use of wooden wheels on the cars upon their road. Quite a number of the wooden wheels have been purchased, and they will be substituted for the present iron ones on some of the new cars. They are understood to cost nearly trebble the price of iron wheels, but are considered quite as cheap in the end. They are made of elm or teak wood, and bound with steel tires. In addition to being less liable to break by the action of frost or otherwise, they make less noise.

George Hudson, the English "ex-railway king," is now in France in an utterly destitute state. A movement was on foot to induce the North-Eastern Railway company to grant him an annuity of £200 a year. Little more than twenty years ago Mr. Hudson (who had previously been a retail dry-goods merchant in a small town) was the most conspicuous man in England, and the titled personages of the land had often to wait for an audience with him.

NEW BOOKS.

The Mines of the West—A Report to the Secretary of the Treasury. By Rossiter W. Raymond, Ph. D., Commissioner of Mining Statistics. J. B. Ford & Company, 39 Park Row, New York.

Congress made a wise move when it appointed Dr. Raymond Commissioner of Mining Statistics, as his preliminary report now before us amply proves. The appointment of scientific experts to positions of this character cannot be too strongly recommended, and while Dr. Raymond's predecessor, J. Ross Browne, did a great work and did it well, still the work which the present commissioner is required to carry on could only be thoroughly accomplished by a scientific man. This will be evident from the letter of instructions furnished by the Secretary of the Treasury, of which the following are the principal points. The most important subjects for inquiry at present seem to be—

First. As to the different processes of treating the ores, their chemical combinations, and the system demonstrated by practical experience to be the most successful.

Second. The relative merits of the various invention machines and mechanical contrivances now in use or projected for the reduction of the precious metals, and for all other purposes connected with the business of mining and metallurgy.

Third. The special needs of the great mining interest; how it can be encouraged and rendered most productive ; how far individual enterprise should be left untrammelled by legislative action, and to what extent and in what instances government might properly lend its aid to facilitate the development of the mines and thus arrest the present annual decrease of the production of bullion.

Fourth. What has been the experience of other countries resulting from the establishment of national institutions for the education of miners, and how far would the systems prevailing in Europe be applicable to our people or appropriate under our government?

In view of the great and increasing importance of our mineral wealth, the weight of the questions here propounded and their intelligent discussion will be evident to all.

Mr. Raymond in his reply to the Secretary of the Treasury, states: "I have not attempted to make it (my report) comprehensive, at the cost of accuracy. It contains my observations and such others as I have collected from perfectly trustworthy sources. The report is in two parts, the first containing such observations of the present condition of our mining industry as I could collect, and the second discussing at considerable length the subjects involved in the relation of the government to that industry. The subject of methods and processes of mining and reduction I have entirely postponed, proposing to treat it in my next report with more care and thoroughness than would have been possible in the brief period and with the limited means at my disposal last year." The report is well and lucidly written, the style excellent, technical or obscure terms are avoided. The report is embellished with profiles taken *on the plane of the view*, which will be found to help very materially in the proper understanding of the subjects discussed. The bullion product for the past year, (1868,) is made to be as follows from official returns and estimates:

California	$22,000,000
Nevada	14,000,000
Montana	15,000,000
Idaho	7,000,000
Washington and Oregon	4,000,000
Arizona	500,000
New Mexico	250,000
Colorado and Wyoming	3,250,000
All other sources	1,000,000
	$67,000,000

"This is a decrease of $8,000,000 from the product of 1867, which showed a falling off of some $8,000,000 as compared with that of the year before. Montana, Idaho and Colorado, manifest a satisfactory improvement; but there is a decrease of $5,000,000 from California, and $6,000,000 from Nevada, the latter being due to the exhaustion of many of the Comstock ore bodies."

"It is an instructive fact that the greater product from deep mining is furnished by the same mines this year as last year and the year before, indicating that a more general adoption of systematic and economical methods would result in greater stability of production. The yield from placer mining must be exhibited to decrease, and its place must be supplied by the cement and quartz mines. The causes of the decrease in our production of bullion may be enumerated as follows:

"1. The exhaustion of many surface deposits.

"2. The reaction following upon a period of excited speculation and the collapse of numerous dishonest schemes.

"3. The increasing and novel difficulties attendant upon the management of deep mines and the reduction of refractory ores.

"4. The lack of communications, capital and knowledge, such as are required for the creation of enterprises based on the extraction and reduction of ores of low grade in large quantity—the only stable form of mining.

"5. The vexations and ruinous litigation which waits upon mining on the public dominion, and which is most troublesome and expensive where mining is, in other respects, most profitable—thus operating to destroy those enterprises which have overcome other difficulties."

"All these may be summed up in one sentence. Mining has been found in too many instances to be unprofitable; and the individuals who have lost money have retired from business. It certainly is not the duty of the government to give bounties to bolster up mining industry, if that industry is by the nature of the case an unprofitable one. Yet it cannot be denied that the decrease of the product of gold and silver in this country is a matter which particularly concerns the government at this time; and it may well be inquired, whether the causes of it are remediable. I believe that time will remove many of them, and that the action of government, based upon a just appreciation of its relations to the mining industry, will do away with the rest. Concerning the extent of our 'mineral resources,' the half has never been told; but those resources are but one factor, which must be joined with labor and intelligence to make the product wealth. When the industry of mining in these rich fields is based upon a foundation of universal law, and shaped by the hand of educated skill, we may expect it to become a stately and enduring edifice, not a mere tent pitched to-day and folded to-morrow. This industry has been the pioneer in our far-western territory. It has founded State, attracted population, enlarged the boundaries of civilization, and it has done this great work in a lawless and careless way, without much regard to the future. I believe that with the extension of the government surveys over the public domain, and the reduction of its vast area to order and law, the consolidation and definite adjustment of the mining interests will become imperatively necessary; and inasmuch as mining out runs all other activities in our new territories, and needs more than any other the aid of judicious legislation, I believe it should receive immediate attention."

We have quoted Mr. Raymond's reply to the Secretary of the Treasury thus extendedly, because his views are of such a practical character, and so worthy of the serious consideration of our people. We feel that our government, so liberal in its legislation in other matters—has not taken hold of this branch of our material wealth in a manner which the importance of the subject demands. We find that the most intelligent portion of our population does not comprehend the vast latent power—the power of gold and silver—which lies buried in the slopes of our great mountain chains of the west. The one individual fact that the Comstock Lode, of Nevada, has produced since its discovery in 1860, *one hundred millions of dollars*, should be sufficient to show that there is no single branch of industry in our land more worthy of thorough systematic, scientific development than that of mining. It is true that mining partakes of the lottery element to some extent, for one day the miner "strikes it rich" and the next day he may be in non-productive ground, but this is equally true of any business, however judiciously carried on. The curse of the west has been the formation of vast companies with bogus capital, and incompetent managers in charge of the mining operations. Companies made up of our best eastern capitalists have employed and continue to employ men as mining superintendents, who have not the first preliminary qualification which would fit them for their positions; these very business men who are so cautious in the employment of clerks or bookkeepers in their private business, exhibit the most remarkable lack of business ability in appointment of men to take charge of so important an undertaking as that of the development of a mine or the inauguration of metallurgical processes. We have known mining superintendents at the west who had never seen a mine until their arrival on the ground, and who did not know the difference between iron pyrites and native gold. Is it to be wondered at in view of these facts that mining operations—as a whole—have not been successful. At some future time we shall probably take occasion to discuss this subject of the employment of competent engineers in this branch of industry.

Part first of the report is devoted to observations on the present condition and prospects of the mining industry.

In his remarks on the New Almaden mines, Mr. R. says: "The quicksilver trade of the world is substantially an armed truce between Spain and California. The mine of Old Almaden, in Spain, supplies the market of London and a large part of Europe, and ships as far west as the city of Mexico. The New Almaden Co. got control of the Chinese market by underselling, and supplies of course the American demand, so that the world is about equally divided between these two companies. During the year 1868, the New Almaden produced 1,960,236 pounds quicksilver. Accounts of the principal mines on the great mother lode of California are given, together with the deep placers of Nevada county. A valuable chapter on the comparative merits of giant powder and common powder. The largest portion of the first part of the report is naturally devoted to Nevada, the mines of the Comstock being treated considerably in detail. The White Pine district and its wonderful deposits, comes in for a good share of attention. As an example we extract a portion of the account of the "Eberhardt" mine, its name having become almost synonymous with that of the cave entered by Aladdin." "At a depth of twenty or thirty feet from the surface drifts have been run in all directions *through solid masses of chlorides* or other ores of silver for twenty—fifty feet, and the end is not yet reached. Descending the shaft we found ourselves among men breaking down silver by the ton. The light of our candles disclosed great black sparkling masses of silver ore on every side. The walls were silver, the roof over our heads silver, the very dust which filled our lungs and covered our boots and clothing was a gray coating of fine silver. From a chimney in the Eberhardt ground $85,000 worth of silver was taken in a few days. One of the owners of the Eberhardt, but recently a poor man, values his interest at $1,000,000."

Since the above was written many other locations of equal value are claimed to have been made.

The notes on Montana, Arizona and other territories are not very extended, having been furnished to the commissioner by other parties; these territories will receive greater attention during the coming summer.

Part second, on the "Relations of Government to Mining," is a most important part of the report. The subject is discussed under the following heads:

Mining and Mining Law among the Ancient.

Mining Law in the middle Ages.

The Spanish Mining Law.

Modern German Codes. The Code of France. Mining Laws of England and Canada, and finally mining education, under which head accounts—with the course of instruction—are given of the Freeberg, Berlin, Clausthal and Paris Schools. In this second part information is given which cannot readily be obtained elsewhere. M.

CHEFS D'ŒUVRE OF THE INDUSTRIAL ARTS. (By PHILIPPE BURTY.) POTTERY AND PORCELAIN, GLASS, ENAMEL, METAL, GOLDSMITH'S WORK, JEWELRY AND TAPESTRY. Illustrated. Edited by W. CHAFFERS, F. S. A. London: Chapman & Hall, Piccadilly. 1869. Sold by Van Nostrand, N. Y.

Although this is not an engineering book, the subjects treated are of more than incidental importance to the engineer and the mechanician. There is much practical information concerning the processes and machinery of ornamental construction, but the charm of the book is thus expressed, at the close of a long review, in the "Builder":

To look carefully over this work brings an impression into the mind exactly like that which occupies it after a long day spent in the South Kensington Museum, or in the Louvre, or in the Vatican. And it also brings a desire to visit those courts and *salles* again, to see the lordly dishes and other triumphal specimens of the great ceramists, the clever, dainty, cunning enamels, the bronze and iron work of departed centuries, the sumptuous goldsmith's work and sparkling jewelry, with the new lights its perusal has conferred.

THE HISTORY AND PROGRESS OF THE ELECTRIC TELEGRAPH, WITH DESCRIPTIONS OF SOME OF THE APPARATUS. By ROBERT SABINE, C. E. Second edition, with additions. London: Virtue & Co. 1869. Sold by Van Nostrand, N. Y.

The following are the principal points in this work—early observations upon electrical phenomena, telegraphs by frictional and voltaic electricity, and by electro-magnetism and magneto-electricity. An excellent and most useful description is given of the various telegraphs now in use. Treating of construction, we find a large amount of information on overhead and submarine and underground lines; and the final chapter is given to atmospheric electricity. We feel sure that this edition, containing so much and such useful matter to the practical telegraphist, will be welcomed by all engaged in the profession as a most useful addition to their telegraphic library.—*Mechanics' Magazine.*

HANDBUCH FUR SPECIELLE EISENBAHN-TECHNIK, ETC VON E. HEUSINGER VON WALDEGG. Engleman, Leipzig, 1869. 8 vo., illustrated.

The first part of this work, which is promised to be completed in four parts, has appeared, and it is probable that it will prove the most complete and encyclopædic work upon every branch of railway construction and plant, bringing down the subject to the existing date, that has yet appeared. This first part commences with an able sketch (not everywhere absolutely free from slight errors) by Von Weber, Director of State Railways at Dresden, of the rise, progress, and history of railways. The remainder treats of the substructure of the way (without dealing with bridges, viaducts, etc.), of the table, ballasting, permanent way, fastenings, etc., of which copious details of all the many varieties on the German, American, and other lines are given; and with the manufacture, verification, choice, etc., etc., of rails, including the Bessemer manufacture of steel rails. There is a chapter of some interest upon the theoretic principles of the resistance of rails laid into way. One excellent feature of this really fine work, which is well illustrated both with engraved plates and by woodcuts in the text, is a very complete bibliography and reference, at the end of each chapter, to all published papers upon its particular subject. These lists are chiefly of German works, but also contain those in most of the other European languages. The book is wonderfully cheap, considering its illustrations. We cannot say we have met with anything perfectly new to us in this first part.—*Practical Mechanic's Journal.*

APPLEBY'S ILLUSTRATED HANDBOOK OF MACHINERY AND IRON-WORK. By APPLEBY BROTHERS. E. and F. N. Spon, 48, Charing-cross.

We have here a handsomely published volume of some 450 pages, which endeavors to appear as little like a catalogue as possible, but with very indifferent success. As a general catalogue it is admirable, containing, as it does, between three and four hundred wood engravings, and the prices of at least two thousand machines and miscellaneous articles. The first section is devoted to drawings and prices of steam cranes, travelers, winches, and steam-hoisting machinery; the second to engines, boilers, turbines, and dredgers; the third to steam and hand pumps, hydraulic machinery, motors, and fittings; the fourth to contractors' plant, the fifth to machine tools, and the sixth principally to agricultural implements. Added is a small collection of tables, memoranda, and information for engineers, possessing no great merit, and open to considerable improvement. But, as a price-book of general machinery, Appleby's handbook is more complete than any which has yet been brought under our notice.—*Engineering.*

THE ELASTICITY, EXTENSIBILITY, AND TENSILE STRENGTH OF IRON AND STEEL. By KNUT STYFFE, Director of the Royal Technological Institute at Stockholm. Translated from the Swedish. With an Original Appendix by CHRISTER P. SANDBERG, Assoc. I. C. E. With a Preface by JOHN PERCY, M. D., F. R. S. John Murray: London. 1869. For sale by D. Van Nostrand, 23 Murray street, New York.

This work is attracting great attention among iron and steel makers and constructors. It is reviewed and quoted at great length by "Engineering," "The Engineer," and other authorities. It contains the result of a series of experiments conducted by a committee appointed by the King of Sweden, with the view of examining railway plant of home manufacture, and of determining the fitness of Swedish iron for such materials. The experiments were spread over several years, and had reference to the elasticity, "extensibility," and absolute strength of different varieties of iron and steel. The tests were carried out under the direction of Professor Knut Styffe, director of the Royal Technological Institute at Stockholm, a gentleman whose lifelong training in experimental science eminently qualifies him for the task he has undertaken. It is no small recommendation of the author which Dr. Percy gives in his preface to the work: "From the high position which I know he occupies in the estimation of scientific men in Sweden, perfect confidence may be placed in the accuracy of his results, though his conclusions may not in every case be accepted." The volume contains a large amount of information, carefully collected from trustworthy experiments; it is illustrated with numerous, although not very artistic, working drawings. An eminent authority on such matters—viz., Mr. Fairbairn, writes: "I have great pleasure in bearing my testimony to the scientific and practical value of your translation of this important work, and, looking to the innumerable uses to which this material is applied, I have no hesitation in recommending it to the perusal of the architectural and engineering public." The author divides his book into four chapters, the first treating of experiments on tension at ordinary temperatures; the second, of the application of the results of these investigations to the determination of the relative values of steel and iron, and of the different varieties of these materials, for different purposes; the third, of experiments on tension at high and low temperatures; and the fourth, of experiments on flexion at different degrees of temperature. To these chapters are added various tables and plates, and also a valuable appendix by Mr. Sandberg.

The work, however, useful as it is in many particulars, is severely criticized. "The Engineer" pronounces it impractical and obscure, although painfully precise. Many of the considerations are quite new to iron workers in this country, at least, and will be farther referred to.

DISINFECTANTS AND DISINFECTION. By ROBERT ANGUS SMITH, Ph. D., F. R. S., F. C. S. Edinburgh: Edmonston and Douglas, 1869. For sale by Van Nostrand, New York.

By common consent, Dr. Angus Smith has become the first authority in Europe on the subject of disinfectants. To this subject he has devoted a large portion of his scientific life; and now, in a compact volume of only 138 pages, he has condensed the result of twenty years of patient study. We cannot too much commend the plan and execution of this inquiry. Almost every page contains evidence of exhaustive, laborious research, guided in its course by the clearest judgment. We seek in vain for some weak point to give us occasion to air our critical acumen. Our duty, therefore, must be confined mainly to giving extracts—criticism being out of the question—for no man living is competent to criticise Dr. Angus Smith on disinfection but Dr. Angus Smith himself—*Chemical News.*

THE MILLING JOURNAL AND CORN EXCHANGE REVIEW. New York: J. D. Nolan & Co. Publishers, 95 Liberty.

The number of American journals devoted to special subjects is receiving constant additions. We have just received a copy of a new monthly journal devoted to the subject which its title, given above, indicates. The milling businees is one of vast magnitude in this country; and we should think there is a fine opening for a paper treating of it. The copy before us gives fair promise of success.

The above notice is from the "American Artizan;" we can fully indorse it, and we may add that the new journal has more practical information than most of the journals among us, that treat of special features of science and mechanics. Milling is a subject of sufficient scope and importance to require quite as good a special organ as for instance telegraphy and gas lighting, and this demand is likely to be supplied, if the mill managers and mechanicians especially interested do their part. They will be the losers if such a journal is not properly encouraged.

THE AMERICAN MILLER AND MILLWRIGHT'S ASSISTANT. By W. C. HUGHES. Price $1.50 post paid. Same publisher.

This is another extremely useful work on milling, and will be found a most acceptable compendium for references. It embodies the best information derived from the author's personal knowledge and practical experience. Few intelligent millers, we are persuaded, will long remain without it. It is a plain, practical treatise, written in a style which will be easily understood, and cannot fail to be of incalculable value to apprentices, and others, who have a desire to perfect themselves in every branch of milling.—*Milling Journal.*

THE AMERICAN YEAR BOOK AND NATIONAL REGISTER FOR 1869. Edited by DAVID N. CAMP. Hartford: Published by O. D. Case & Co.

This work is the initial volume of a proposed annual publication, respecting the affairs of the General and State Government, public institutions, finances, resources and trade of this country; the political, financial and social conditions of other countries; and various other subjects relating to social and political economy. The work is a thick 8vo., printed and bound in excellent style; and seems a valuable work of reference.

THE PHENOMENA AND LAWS OF HEAT. By ACHILLE CAZIN. Translated and Edited by ELIHU RICH. pp. x., 265. New York: Charles Scribner & Co.

We have here an additional volume in the series of popular works on the wonders of science, which Scribner & Co. have recently introduced into this country. It is written in a style entirely intelligible, even to persons without scientific training, and the numerous illustrations add greatly to the interest of the text.

Law of Patents for Inventions; with Explanatory Notes on the Law as to the Protection of Designs and Trade-Marks. By F. W. Campin. London: Virtue & Co. 1869.

This book is highly recommended, and reviewed at length in "Engineering," which authority says: "Mr. Campin's book throws a clear light upon the subjects of patents and patent law in all its stages, and is illustrated by a host of the most pertinent cases."

Although the details of proceedings in the British Patent-Office are of limited importance to others than professional solicitors of patents in this country, the elucidation of British patent law is valuable to all men, here as well as in England, whose claims are or are likely to be involved. British precedents are as much relied on in our courts as at home.

MISCELLANEOUS.

ENGLISH AND FRENCH MEASURES.

From "The Engineer."

Lengths—Longueurs.

1 inch = 0.0254 mètres
1 foot = 0.3048 mètres
1 yard = 0.9144 mètres
1 chain = 20.1160 mètres
1 mile = 1609.315 mètres
1 millimètre = 0.394 in.
1 centimètre = 0.3937 in.
1 mètre = 3.281 ft. = 3 ft. $3\frac{3}{8}$ in.
10 mètres = 32.809 ft. = 10.936 yds.
1 hectomètre = 100 metres = 328.090 ft. = 109.363 yds. = 4.971 chains
1 kilomètre = 3280.90 ft. = 1093.63 yds. = 49.71 chains = 0.621 miles
1 knot = 6082.66 ft. = 1.152 miles = 1853.931 mètres
£1 per mile = 15.525f. per kilomètre
100f. per kilomètre = £6.437 per mile.
1f. per mètre = 8.778d. per yd. = 2.926d. per ft.
1s. per yard = 1.367f. per mètre
1s. per foot = 4.101f. per mètre
1 kilomètre = 0.539 knots

Areas—Superficies.

1 square inch = 6.4513 c|m^2
1 square foot = 0.0929 m|^2
1 square yard = 0.8361 m|^2
1 rod = 25.2919 m|^2
1 acre = 0.4047 hectare
1 mm|^2 = 0.00155 square inches
1 c|m^2 = 0.1550 square inches
1 m|^2 = 1.1960 sq. yds. = 10,7643 sq. ft.
1 are = 100 m|^2 = 0.0247 acres
1 hectare = 10,000 m|^2 = 2.4711 acres
1s. per square foot = 13.455f. per m|^2
1s. per square yard = 1.495f. per m|^2
1f. per m|^3 = 8.0266d. per square yard
£1 per acre = 61.778f. per hectare
100f. per hectare = £1.6188 per acre
100f. per are = £0.0162 per acre

Measures of Capacity, Dry and Liquid—Mesures de Capacité pour les Liquides et les Grains.

1 pint = 0.5679 litres
1 quart = 1.1359 litres
1 gallon = 4.5435 litres
1 peck = 9.0869 litres
1 bushel = 36.3477 litres
1 sack = 1.0904 hectolitre = 109.0430 litres.
1 quarter = 2.9078 hectolitres
1 chaldrou = 13.0852 hectolitres
1 litre = 1.7608 pint
1 decalitre = 2.201 gallons
1 hectolitre = 22.010 gallons
1s. per gallon = 0.2751f. per litre
1f. per litre = 43.618d. per gallon

Volumes.

1 cubic inch = 16.3870 c m^3
1 cubic foot = 0.0283 m|^3 = 28 litres
1 cubic yard = 0.7645 m|^3 = 765 litres nearly
1 c|m^3 = 0.061 cubic inches
1 d|m^3 = 1 litre = 0.0353 = 61.028 cub. in.
1 m|^3 = 1.3079 cubic yds. = 35.322 cub. ft.
1 m|^3 of distilled water (*eau distillée*) = 1 *tonneau de mer*, weighing 1000 kilogrammes
1s. per cubic foot = 44.150f. per m|^3
1s. per cubic yard = 1.6349f. per m|^3
1f. per m|^3 = 7.339d. per cubic yard = 0.272d. per cubic foot

Power—Force.

(Horse-Power, H. P.—Force en Chevaux.)

1 H. P. is the force that will raise 33,000 lb. to a height of 1 foot in 1 minute.

1 *cheval-vapeur élève* 33,000 *lb. à* 1 *pied de hauteur en* 1 *minute; ou* 75 *kilogrammes à* 1 *mètre en* 1 *seconde.*

1 kilogrammètre is the force that will raise 1 kilogramme to a height of 1 mètre
1 H. P. = 75 kilogrammètres per seconde
1 Dynamie = 1000 kilogrammètres

Pressures—Pressions.

1 lb. per square inch = 0.0703 kilos per c|m^2
1 kilo per centimètre = 14.229 lb. per sq. inch.
1.033 kilo per centimètre = 14.73 lb. per sq. inch = 1 atmosphere

Railway Earthworks—Terrassements.

1000 cubic yards per mile = 474.755 m|^3 per kilomètre
1000 m|^3 per kilomètre = 2104.823 cubic yards per mile

Rails.

1 lb. per yard run = 0.4958 kilos per mètre
1 kilogramme per mètre = 2.0168 lb. per yard = 0.6723 lb. per foot

A Model Establishment.—It is a remarkable fact that Mr. Krupp—in business for forty years, and with not less than 10,000 men for some years in his employment—has never had a dispute with a workman; a fact, doubtless, ascribable in a great measure to the admirable institutions and regulations for the benefit of the workmen. By one of the provisions of the establishment, every workman becomes entitled, after twenty years' work, to a retiring annual pension of half his last year's salary, and after thirty-five years he may retire on full pay. Such regulations, however effective they may be, do not appear to explain the extraordinary concord and order perpetually maintained in this enormous establishment. From 1,000 to 1,400 men are frequently engaged at one operation, such as casting an ingot. They work as one man, and the same harmony and regimental order prevails throughout. It is, doubtless, traceable, in part, to the military training which every Prussian receives. —*Fortnightly Review.*

A New Movement.—*Apropos* of the article on another page, relative to the perfecting of existing American Scientific Schools, we are happy to learn that the alumni of the Rensselaer Polytechnic Institute, at Troy, propose to assemble at that place on the 22d and 23d of June next, for the purpose of forming themselves into a permanent association; partly, no doubt, for the purpose of inquiring into, and intelligently representing throughout the land, the interests of that Institution, which, in certain respects, have long been strangely and lamentably neglected. We hail this movement with great pleasure from every point of view. It is, we believe, the first one of its kind in the country; that is, the first made by the graduates of any of our Technical Schools. It will rally to the support of an old and honored institution the affections and counsels of an able body of graduates, and will naturally stimulate effectual inquiry into its wants, and the reasons why they have been so loug unsupplied, and the best means of meeting them. It will naturally still further attract the friendly attention of the whole engineering profession throughout the land to au Institution which, amid many discouragements, has striven indefatigably to honor that profession by raising the standard of entrance upon it. It will thence properly cause the Institute to be more widely known and appreciated by the general public. We have seen the circular, calling the meeting, which is sent to every accessible graduate, and take pleasure in here giving publicity to the proposed movement, in order that all concerned may be the more sure to be advised of it, and may be the more certain to attend.

The Dust of Cities and the Health of Men.—A microscopist (Mr. Dancer, F. R. A. S.) has, says the "Daily News," been examining the dust of our cities. The results are not pleasing. In every specimen examined by Mr. Dancer, animal life was abundant. But the amount of "molecular activity" is variable according to the height at which the dust is collected. And of all heights which these molecular wretches could select for the display of their activity, the height of five feet has been found to be the favorite. Just at the average height of the foot-passenger's mouth these moving organisms are always waiting to be devoured and to make make us ill.. A large proportion of vegetable matter also disports itself in the light dust of our streets. Mr. Dancer's observations show that in thoroughfares where there is much traffic a large proportion of this vegetable matter thus floating about consists of what has passed through the stomachs of animals, or has suffered decomposition in some way or other. This unpleasing matter, like the "molecular activity," floats at a height of five feet, or thereabouts. These observations tend to a recognition of the manner in which some diseases propagate themselves, and the lesson to be deduced is that the watering cart should be regarded as one of the most important of our hygienic institutions. Supplemented by careful scavengering it might be effective in dispossessing many a terrible malady which now holds sway from time to time over our towns.

Screw vs. Paddle.—The splendid Cunard paddle steamer Persia has been sold for £15,000. Meanwhile no paddle steamers are building for the Atlantic lines. The Pacific Mail still sticks to paddles.

The Channel Bridge.—It appears from the French papers that a proposal has been made to M. Boutet, the projector of this enterprise, to undertake the connection of the town of St. Malo with the French coast by a causeway or viaduct, constructed on his system, and that the Anglo-French Channel Bridge Company are about to undertake this work. The town of St. Malo stands upon an island, distant from the mainland, with which, however, it is in some measure connected by a causeway, usually covered by the sea. A road raised upon a bridge such as M. Boutet has proposed for crossing the Channel, would, therefore, be a great advantage to such a locality, and it would afford the company an excellent oppoitunity of demonstrating the feasibility of M. Boutet's mode of construction, which, indeed, seems to be pretty well acknowledged in Paris. The proposition forms the subject of a very elaborate criticism in the February number of "Le Genie Industriel," a valuable and influential French work, which has been long devoted to the examination of leading scientific works. The writer of the article in question, M. Fieort, demonstrates the theoretic soundness of the principles on which M. Boutet relies.—*Mining Journal.*

The new P. & O. Steamship "Deccan."—This vessel is the latest addition to the Peninsular and Oriental Company's fleet. Her dimensions are as follows: Length betwcen perpendiculars 345 feet; breadth of beam 42 feet; depth of hold 30½ feet; builder's measurement 3,001 tons; gross tonnage, 3,128. Her engines are of 600 nomiual horse-power (indicating 2,730 during her trial); diameter of cylinders 76 inches, and length of stroke 4 feet; and has a four-bladed propeller 18 feet 10 inches in diameter, with a pitch of 27½ to 30½ feet, aud weighing 12¾ tons. Two runs at the measured mile showed the following results:—Steam, 25 pounds; vacuum, 28 inches; revolutions, 52; the true mean speed being 13.733 knots per hour, with a mean draught of 18 feet 8¼ inches. The heating surface of the boilers is 12,504 square feet, fire-grate surface 420 square feet, and condensing surface 5,864 square feet.

Drying Green Wood..—A new method for drying green wood in a very short time, says the "Builder," consists in boiling it for some hours in water and leaving it then to eool, by which the soluble substances are removed. It is then boiled in an aqueous solution of borax, by which the insoluble albumen of the wood is rendered soluble, and escapes from the pores. The wood is then placed in drying-chambers, heated by steam, and allowed to remain three days.

American Institute.—The vacancy in the Faculty of the American Institute, caused some three years since by the death of Prof. James J. Mapes, has been filled by the appointment of James A. Whitney, associate editor of the "American Artisan," as Professor of Agricultural Chemistry.

Technical Education.—The English Government have decided not to establish schools of technical education throughout the country, as the expense would be enormous. They have resolved, however, to give liberal support to local efforts made for this purpose.

The French Atlantic Cable will be laid in June. Its length will be 3,564 nautical miles, from Cape Ushant, a few miles from Brest, via the French Island of St. Pierre (near Placentia Bay, Newfoundland), to Cape Cod, landing at Plymouth, Massachusetts. The cable will be an improvement in every respect, upon that of 1865-6. It will weigh 400 instead of 300 pounds to the mile. The London Times says: "the standard of the manufactured value of a cable is judged by what are called its units of resistance to the passage of the electric current through the conductor, and the more perfect the insulation the greater that resistance will be. This resistance, measured by the galvanometer, is counted by millions of units. The Indian Government insisted on the Persian Gulf cable having a resistance of 50,000,000 of units. The standard of the Atlantic cable of 1865 was raised to 100,000 units. In the cable of 1866 the standard was raised to 150,000,000 units, and in this French cable the contract standard is 250,000,000 units of resistance and no less; and in this high electrical condition it will be laid. After it is laid every day will improve its insulation. Thus the two Atlantic cables have gained so much in insulation since they left the factory that often during last year, it is said, they gave a resistance as high as 4,000,000 units."

Granite Paving v. Macadam.—The question of the relative durability and safety of these two methods of covering metropolitan streets and roads has undergone much discussion lately by the various vestries, and as it is beginning to be discovered that paving is cheaper in the long run, it is likely that a great deal of paviors' work will be done in the metropolis within the next two years. The advocates of granite cubing seem to be in a majority everywhere, and financial difficulties only stop the way in most cases. The employers of horse power throughout the metropolis prefer paved roads, and no wonder when in the course of the year so much rough unconsolidated broken granite has to be traversed by them, to the injury of the animals, and to the detriment of springs and wheels. Those who object to paved streets on account of the increased noise of the traffic have, to a great extent, to thank the barbarity of modern road making for the development of the present movement in favor of paved roads. The adoption of the steam road roller would not only have been an act of humanity towards our horses, but it would have enabled macadamised roads to be kept in constant repair at a far less cost than by the present slovenly method. —*Building News.*

Steam-Engines and Machinery.—The returns as to the exports of machinery and steam-engines from the United Kingdom for the first 11 months of last year are sufficient to enable us to form a pretty good estimate as to the year's business. We sent last year fewer steam-engines to France, Egypt, British India, and Australia. Russia, however, came to the rescue, and took our steam-engines to the value of £260,537 in the 11 months ending Nov. 30 last year, as compared with £66,522 in the corresponding 11 months of 1867. The falling off in the demand for railway engines in British India rather seriously prejudiced the general result of last year's operations; to Nov. 30 however, we sent abroad steam-engines to the value of £1,598,-795, as compared £1,829,578 in the corresponding eleven months of 1867, and £1,611,442 in the corresponding 11 months of 1866. In the year 1858 we only exported steam-engines to the value of £1,097,278, so that the general course of this branch of our exports is onwards. The exports of general machinery showed very little variation, upon the whole, last year, but the case would have been otherwise but for the augmented demand from Russia.

Enameling of Iron Vessels.—The enameling of saucepans and other articles in wrought or cast iron has long been practiced, a very fusible enamel reduced to powder being sprinkled ovey the surface of the iron when heated to redness; but as the mixtures employed consist of highly alkaline silicates, the enamel is not very durable, and will not withstand acids or even salt liquids. An improved process has been introduced in France. The metallic surface is brought in contact with the ingredients of ordinary white glass, and heated to vitrification; the iron is said to to oxidize by combination with silicic acid, and the glass thus forms one compact body with the metal. The coating of enamel may be laid on as thinly or as thickly as desired, but a thin coating is better as regards the effect of expansion or dilatation. Experiments are being made in coating the armor plates for ships in the manner above indicated.—*Scientific American.*

Architectural Library.—The New York chapter of the American Institute of Architects propose to establish in New York a library of works on architecture and the cognate arts for the benefit of students, not of architecture only, but of those branches known as industrial designing. The excellent tendency of such an enterprise is obvious. The more our architects know, the better and more economical will our buildings be. The members of the Chapter have already begun a subscription, and those who are interested should apply to Alfred J. Bloor, Secretary, 42 East Fourteenth Street, New York.—*Harper's Magazine.*

Education.—A Convention of American Philologists will meet at Poughkeepsie on the 27th of next July, to consider some very practical questions, as, How much time in college should be given to the study of language? How much to modern languages? What is the best method of instruction in the classical language? What position should be given to the study of the English language in colleges and high-schools? The call is signed by many of the most noted instructors and scholars in the country, and the meeting will undoubtedly be both interesting and serviceable.—*Harper's Magazine.*

Great Art Prize in France.—In the month of August is to take place the first award of the great prize of 100,000f. instituted by the Emperor Napoleon III. to be voted by the Academy of the Beaux Arts and the Institute of France to the French artist, painter, sculptor, or architect who shall have produced, and entirely completed within the five years preceding the time of the award, a work of great excellence. The jury is to consist of thirty members—ten sculptors, ten painters, and ten architects. In case any of the members of this jury should become candidates for the prize, they will retire from it, and their places will be filled up by the Academy.—*Building News.*

PAPERS ON CONSTRUCTION.

No. III.

RELATIONS OF SAFE LOADS TO ULTIMATE STRENGTH.

By Lieut. C. E. Dutton.

(Continued from page 501.)

A comprehensive series of experiments, united with exhaustive theoretical investigation into the relation of safe loads to ultimate strength is greatly needed. Not merely are there wide differences in the practice of the most accomplished engineers in this respect, but even the fundamental principles upon which the various practices are founded seem to be arbitrary rather than rational. In England, where experiences have been wider, and where the economical aspects, certainly, of engineering have been more assiduously cultivated, the arbitrary character of practice is a marked feature. Thus, the Board of Trade regulations prescribe that the working load shall never subject any part of an iron structure to more than five tons of tensile strain per sq. inch. It is obvious that the nearness of this standard to the highest economy will depend, in a great measure, upon several considerations, either one of which may modify extensively its value. First, the resistance of wrought iron to crushing is less than to extension, whether we take its ultimate resistance or its moduli of elasticity. The ratio of these two resistances may be stated at $\frac{4}{5}$, so that if five tons per square inch are just a safe load for tensile strains, they are unsafe for compressive strains; and since, in girders of a symmetrical cross section, these two strains are equal, the fallacy of such a standard becomes apparent. Secondly, the qualities of different grades of iron differ widely both in respect of tensile strength and homogeneity; and, it may be added, in the ratio of tensile to compressive resistance—circumstances whose modifying effect is too plain to need comment. Thirdly, the details and kind of structure may be such that vital parts may be exposed to strains more complicated than simple tensile or compressive stress, the exact nature of which may not be fully ascertained nor contemplated in such an estimate of strength.

Other considerations may also be suggested, which show, in the aggregate, that no such arbitrary standard can insure the highest economy of strength consistent with perfect safety. The wide differences of opinion on this subject may be illustrated by stating that when, a few years ago, it was made a subject of special inquiry by Parliament, Mr. Glynn, in his evidence, recommended that a cast iron bridge should never be loaded beyond one-tenth of its ultimate strength. Mr. Stephenson and other accomplished builders recommended one-sixth, and Mr. Brunel thought one-third, or even two-fifths, a safe margin. Perhaps there is less, much less, difference in the practice of to-day than in that of twenty years ago; the various factors of safety ranging, generally, between one-fourth and one-sixth. But even here it may be fairly asked, how much of this approach to uniformity is merely arbitrary, and how much is founded upon sound theory and carefully considered practical and experimental results. Probably a great deal of the former, and very little of the latter.

With the increased knowledge now possessed of the nature and properties of iron, and its behavior under loads, it would seem that a series of experiments might be instituted with a fair prospect of most valuable results. In the smaller structures, which are thrown up daily in our cities and over streams, the matter may not possess such vital importance, though even here the frequent failures recorded call loudly for reform.

But the tendency of to-day is towards structures which, a few years ago, would have been thought as romantic as air castles, and in these economy possesses a vital importance; indeed, may frequently constitute just the difference between the practicable and the impracticable. With every increase of size the weight of a structure bears a larger ratio to its strength, so that, with given proportions of members, it is easy to calculate the limit at which the whole available strength of it is employed in sustaining its own weight. It is clear, then, that every new acquisition of knowledge which will enable us to determine, with tolerable certainty, the smallest margin of safety, amounts to an extension of the limits of practicability, and to a decided facility in constructions within those limits. We hope to indicate the directions in which theoretical and experimental research may become useful, and the facts which may be made the basis of investigation.

1. The behavior of materials, particularly of iron and steel, under those strains which can be produced experimentally, should be especially and primarily noticed. It seems to us that the use of the ultimate strength of iron, as a standard of reference in determining its available strength, is bad in principle. Ultimate strength, in its general acceptation, means the resistance of a standard bar or rod of the material to rupture by forces applied to it *when new*, and applied, too, during a very brief portion of time, possibly only once. The testing machines usually employed exert their power upon bars of metal fresh from the forge, and rend them by a single effort in a few seconds or minutes. There is, in all this, nothing analogous to rupture produced by protracted wear and tear. We must consider, not merely the well known fact that materials change their molecular structure by time, and the long continued and repeated applications of forces, but that the amount and kind of change so effected, and the exact results upon its strength are quite unknown.

2. Still more pertinent to the case is the fact that the ultimate strength is of little consequence, because no structure must be subject to strains beyond the limits of elasticity. The force under which marked and permanent changes take place in the forms or dimensions of the materials used is necessarily without the limit of safety, for our knowledge of materials assures us that in such a case rupture is merely a matter of time. This lower limit, then, is the only one which practically bears upon the case, and its relation to the higher one of ultimate strength is by no means understood. It is even doubtful whether any definite relation exists at all.

Experiments upon the ultimate tensile strength of materials have been numerous and almost exhaustive. Nearly every book treating of materials contains tolerably complete tables, both of tensile, compressive and transverse strength, determined experimentally. What is far more essential is a reliable table of strains at which these same materials begin to elongate, or collapse into permanent set. To deduce these strains from the ultimate strength is impossible, as the following examples, found in Barlow, will show. The experiments were made by Mr. Brunel.

No.	Began to stretch. Tons per sq. in.	Breaking weight. Tons per sq. in.	No.	Began to stretch. Tons per sq. in.	Breaking weight. Tons per sq. in.

Mean,	22.2	30.4	....	24.44	32.3

The iron used was the best Yorkshire, hammered in rods $\frac{3}{8}''$ and $\frac{1}{2}''$ square.

We must here lay down, as well as we are able, what we understand by the limit of elasticity in any particular case. In the preceding table the specimens ostensibly begin to change their forms and dimensions under a stress somewhere near three-fourths the breaking stress. But it is well known that both wrought and cast iron take permanent set at far lower stresses. Indeed, it is asserted by some eminent authorities that any application of force, however slight, will produce permanent change in iron, though the change may be so small as to escape detection by the most delicate measurements. Allowing this to be true (for there is no intrinsic improbability in it, although it has no practical importance) is there any essential difference between the set produced by the application of twenty tons per inch, and that by the application of one ton, excepting the difference in degree; in other words, is there any essential difference in the nature of the changes produced by the two cases in the molecular arrangement of the material? We venture to suggest that there is an essential difference. It is well established, by many experiments, that iron stretched by weights not exceeding, say, one-third the ultimate strength, resumes *nearly* its original dimensions; but not exactly. The difference is called the set. We are left to infer that this difference is the result of certain molecular changes, but can only surmise their character. Some light may be thrown upon the subject by connecting together the following facts. All varieties of iron consist of agglomeration of minute crystals, octahedral in their fundamental forms, but in most cases also fibrous or minutely acicular, both in cast or wrought iron. The major axes of these crystals have a tendency towards parallelism; *i. e.*, the axes of a considerable portion of the crystals are parallel, or approximately so. In wrought iron this tendency towards, or actual, parallelism is produced by the ductile action of rolling or hammering, compelling the molecules to slide over each other in one direction, during which process they most readily assume the acicular or fibrous structure. In cast iron, also, a definite arrangement takes place in parallel facets, by reason of the escape of heat in particular directions (*i. e.*, in lines normal to the nearest surface of the mass) in passing from the fluid to the solid state. It is not essential to the fibrous condition that all, or nearly all, the crystals should be parallel, but that a considerable portion of them should be so, sufficiently to indicate a tendency to parallelism in a particular direction in preference to any other.

In the case of wrought iron, when the peculiar action of rolling and hammering is considered, it is more than probable that some of the fibers are left in a state of initial tension, and others in a state of initial compression. Under such conditions the application of even a slight degree of force may be sufficient to produce molecular change at points where such tensions exist. In the case of tensile stress, the limit of cohesion between two contiguous atoms may thus be exceeded, and a redistribution of atoms will be most likely to take place by the sliding of other atoms into the interval produced, so that when the stress is removed the tendency to a perfect restoration is resisted at this particular point. In the case of compressive stress, the atoms at points of initial compression may be thrust out of their original situations, and contact effected between atoms which were before separate. and the tendency to restoration after the removal of the stress no longer exists at these points. If we suppose, as is most natural, that these initial forces are of all degrees of intensity between zero and the limit of elasticity, we have here the explanation of the phenomena of permanent set. The effects just described will be approximately proportional to the forces applied. And so we find it very nearly in practice. There are, it is true, departures from the ratio, but not greater than might be expected from the imperfect homogeneity of the metal.

A single application of stress producing a perceptible set, and, according to the views just expressed, occasioning a molecular change in the metal, need not sensibly impair the strength of the iron, for the rearrangement of the atoms may be, and in most instances probably is, as favorable for further resistance as the original one, if not more so. Many repetitions of the stress, however, or the constant action of vibrations during a continuous stress, may produce arrangements less favorable. The tendency to assume the form of large specular crystals seems to be very decided under such conditions, at least, if the strain be tensile. The whole mass being elongated, and the intermolecular spaces being increased, there is afforded, as it were, a sort of facility to the atoms to obey those laws of crystallization inherent in the constitution of all solid matter. Observation and experiment confirm this view.

If there is any measure of truth in the foregoing speculations, it follows that there is a limit of stress at which the cohesive power of every portion will be exceeded, and a general change in the structure of the mass will supervene. If the constitution of the material is such that the atoms can rearrange themselves readily, the material will behave like a tough, pasty mass, elongating considerably, diminishing in size laterally. If it is strongly crystalline, and the atoms refuse to rearrange themselves, rupture is immediate. The former is the case with good wrought iron, and the latter with cast iron.

In a similar connection Mr. Zerah Colburn remarks, "It would be interesting to know the successive positions of the atoms during the application of the strain. We are, however, without any positive knowledge of the positions which the atoms assume in solidification, and under subsequent forging; but the multifarious forms in which all atoms visibly crystallize serve to show us that they cannot all be at equal distances from each other throughout the whole body. If they were, the arrangement would be that of cannon balls in a triangular pyramidal (or prismatic) pile. Could we visibly represent the atoms as occupying the angles of an infinite number of equilateral triangles we should understand that a linear strain, acting to separate any two of the atoms, would, at the same time, draw a third atom, if not a number of atoms, partly between them. And when, from this intrusion, the repulsive force, always enveloping the intruding atom, had once overpowered the attractive or cohesive force existing between the two atoms thus strained apart, these would, in turn, cohere anew to the atom which had been drawn in between them, and thus we should have a permanent rearrangement of the atoms, or, in other words, a permanent set with permanent elongation in one direction, and permanent contraction in a plane at right angles thereto. That the atoms are thus drawn into parallel rows in many kinds of iron, at least, seems evident from the appearance of fracture, which presents stringy collections of particles, forming what is commonly called fibre, although there is great reason for doubting that anything like fibre existed in the iron before it was broken. Mr. Kirkaldy's recent experiments appear to show, as many others have shown, that iron may be made to break short, or to break with an appearance of fibre, just according as it is broken with a sudden blow or gradual pull."

We attach slight importance to the conclusions from Mr. Kirkaldy's experiments, since they furnish only negative evidence, against which may be cited positive evidence of the strongest kind. They merely show that the fibre is not apparent when iron is suddenly broken. On the other hand, it is not only distinctly apparent when it is broken gradually in the direction of its length, but when pieces cut from a bar transversely are pulled asunder the surfaces of rupture give unmistakable indications that we are obtaining a side view of the fibre. Finally, the strength of wrought iron is from two to four times greater in the direction of the assumed fibre than in a direction perpendicular to it, showing that the arrangement of the constituent particles differs widely in the two directions.

We think some confirmation of the views we have set forth will be found in the fact, that rods of wrought iron, subjected to gradual pulls beyond the limits of elasticity, have their strength not only unimpaired, but actually increased by the strain. If the two fragments of a broken rod be submitted again to rupture, the forces required to effect it in each fragment are almost always decidedly greater than that accomplishing the first rupture. This increase of strength will be found to be more decided in proportion to the softness, or ductility of the iron used. Doubtless the same causes which produce this effect produce also the great increase of strength imparted to iron and steel when drawn into wire. Mr. Barlow gives the results of experiments made at the Woolwich dockyard with reference to this phenomenon, which show an increase amounting, in some cases, to 18 per cent. Mr. Colburn mentions the experiments of Mr. Thomas Lloyd, engineer to the Admiralty, on ten bars of Crown S. C. iron, $1\frac{3}{8}$ inches in diameter and $4\frac{1}{2}$ feet long. The mean breaking weight at the first breakage was 23.94 tons per square inch. At the second breakage the mean strength was 25.86 tons per square inch. At the third breakage it was 27.06 tons per square inch. At the fourth breakage it was 29.2 tons per square inch. The mean strength at the last breakage was about 22 per cent greater than at the first. Mr. Colburn suggests, as an obvious explanation, that the bars first broke at the weakest point, then again at the next weakest, and so on. But this seems to disregard the fact that these bars elongated several inches before breaking, which must necessarily involve a complete rearrangement of its constituent atoms throughout its mass, so that the section of minimum strength was constantly altering, if not its position, certainly its ultimate structure. The process, on the contrary, seems to us quite analogous to wire-drawing, the atoms arranging themselves more and more thoroughly in the form of parallel fibres, which is the position most favorable for tensile resistance, until a maximum of parallelism is reached, and therefore a maximum strength.

Taking into consideration the nature and structure of cast iron, it can hardly be expected that it can be as strong after the application of severe strains as before. Rupture must always ensue whenever the elastic limit is exceeded. A continued repetition of strains ought, upon the foregoing principles, to deteriorate the strength by the successive rupture of the cohesion of detached points. Experience in cast iron guns leads to this conclusion, but exhaustive experiments upon various forms, with stresses variously applied, are much needed.

The following valuable considerations by Mr. Colburn are added: "In a paper of great value, read nearly seven years ago before the Royal Irish Academy, and afterwards published in a quarto volume entitled, 'On the physical conditions involved in the construction of artillery,' Mr. Robert Mallet has laid down a useful measure of the working and ultimate strength of iron. Poncelet had already employed co-efficients, which indirectly expressed, not merely the elastic limit and breaking strength of iron, but the range also, through which the force acted in each case, in reaching these limits. Mr. Mallet has adapted these co-efficients to the English standard of mechanical work, viz, 'foot pounds;' and he represents the structural value of different materials, or of different qualities of the same material, in one case, by the product of the elastic load in pounds into half the range in feet, or parts of a foot, through which it acts, and in the other case by the breaking weight in pounds multiplied also by half the range in feet, or parts of a foot, through which it acts. Mr. Mallet employs Poncelet's co-efficients as follows:

$T\,c$ = foot pounds in reaching elastic limit of tension.

$T\,r$ = foot pounds to produce rupture by tension.

$T'c$ = foot pounds in reaching elastic limit of compression.

$T'r$ = foot pounds to produce crushing.

"One-half the weight into the whole extension, or the whole weight into half the extension, is adopted, because the force gradually applied to break the bar must increase from nothing to the breaking weight. Upon Dr. Hooke's law, *ut tensio sic vis*, the weight of a grain will, in some minute degree, deflect or extend the heaviest bar of iron, and the deflection, or extension, will increase progressively with the weight applied, up to the point of rupture. Therefore, if a bar be stretched one foot and then broken with a weight of 33,000 pounds, the work done will be the mean of zero and 33,000 pounds into one foot, or 16,500 pounds. This, as has been said, is the work done in the case of a gradually applied strain. If, however, the weight be applied without impact, yet instantaneously, upon the bar, it will, so long as the limit of elasticity be not exceeded, and supposing the bar to have no inertia, produce twice its former deflection and, therefore, twice the ultimate strain. For the weight, in falling through the distance of the deflection due to the load at rest, will require momentum sufficient to carry it through an additional distance equal to the static deflection. This may be best demonstrated experimentally with the aid of a spring balance. If upon the pan of a balance, sufficiently strong to weigh up to 40 pounds, a weight of 15 pounds be placed, and this be lifted to zero on the scale and there released, it will descend momentarily to nearly 30 pounds on the scale, and were there no opposing resistances, and had the spring no inertia, it would descend to exactly 30 lbs. In the actual application of strains in practice a weight is never thus applied, but a consideration of what would occur under such circumstances is sufficient to show how important it is that vibratory action be not overlooked in considering the strains on bridges. It is to be remembered that this action of suddenly applied loads is only manifested in the case of the application of weights, for if the strain be produced by the sudden admission of steam, or any other practically imponderable body, no additional deflection will take place beyond that due to the pressure acting statically. If steam pressure acted in the same manner, in this respect, as a weight, the steam indicator would show nearly, or quite, double the pressure acting effectively within the cylinder of the engine."

It will not be attempted in the present paper to discuss fully the co-efficients adopted by Mr. Mallet, for there are objections against, as well as reasons in favor, of their application. It is evident that T *r* may be the same in two cases, in one of which a high breaking weight is exerted through a very short distance, and in the other of which a low breaking weight produces stretching through a correspondingly greater distance. But this co-efficient does possess a value in taking account of the combined cohesive force and extensibility of iron, instead of the breaking strength alone. Glass has a high cohesive force, but is uselcss under strain, on account of its brittleness, while india-rubber has great extensibility, or toughness, with but slight cohesion. The products, therefore, expressed by the co-efficients in question do not afford a complete notion of the practical value of a given material, unless the factors whereby these products are obtained are also given. The elastic limit of iron, however low, is not to be exceeded in practical use, whatever its range of elasticity may be; nor does it appear to be prudent to work into the neighborhood of a high elastic limit, when the elastic range is known to be small. It is not to be understood that the co-efficients in question are intended to be applied otherwise than in the comparison of bars of equal length, else it would result that the measure T *c*, in a bar 50 feet long, was one hundred times greater than that of a bolt six inches long, and of the same material and sectional area. For the purposes of the engineer not only is a long bolt no stronger than a short one, but, as it can be no stronger than its weakest part, it will follow that the average strength of 100 bolts six inches long is likely to be greater than that of a bolt of the same diameter 50 feet long. Every engineer is aware of the importanee of toughness in combination with cohesive strength in iron, but we need much more extensive and accurate information respecting the former; and a consideration of Mr. Mallet's co-efficient should lead to additional experiments being undertaken.

Mr. Kirkaldy, proceeding upon an independent course of inquiry, but with the same object as that pursued by Mr. Mallet, published some time ago the results of a series of experiments, which are the first upon any thing like an extensive scale, to take into account the combined cohesive force and extensibility of iron and steel. Mr. Kirkaldy experimented upon hundreds of specimens; but he did not ascertain their limits of elasticity. He has given both the original dimensions and cross-sectional area, and the dimensions and area after fracture, and he has also given the amount of elongation at fracture, although he did not ascertain the amount of extension at the elastic limit. The reduction of diameter of a bar at the joint of fracture serves to give a practical man a good idea of the quality of the iron, but it does not admit of an expression of the mechanical work done in producing fracture, as does the combined breaking weight and linear extension. In tearing a bar in two, also, we have to consider the permanent stretch communicated to all parts alike, and the additional stretch at or near the point of fracture. That part of the stretching which extends uniformly throughout the bar would, we may suppose, be exactly proportional to the length of the bar, while that part of the stretch which takes place close to the point of fracture would, we may also suppose, be a fixed quantity, whatever the length of the bar. Mr. Kirkaldy's specimens of iron and steel varied from 2.4 inches to 8.2 inches only in length, and with these the ultimate elongation at fracture varied from nearly nothing to 27 per cent of the original length, whereas longer bars would have shown a proportionally less elongation. The samples which hardly elongated at all were of puddled steel ship-plates. One sample, which bore 63,098 pounds per square inch of the original area, stretched before breaking but the $\frac{1}{20}$th part of an inch in a length of 7.6 inches, or less than $\frac{7}{10}$ths of one per cent of the length. Adapting to Mr. Mallet's co-efficient, the structural value of such a material would be almost nothing. In fact, Mr. Kirkaldy found the puddled steel plates throughout to have much less extensibility than cast steel plates, and of very irregular breaking strength.

Mr. Fairbairn communicated some of the results of an important series of experiments to the British Association at the Manchester meeting in 1861, from which it appeared that a large model of a wrought iron plate girder withstood, without injury, 1,000,000 applications of a load equal to one-fourth its breaking weight, and afterwards 5,175 applications of one-half its breaking weight, when it broke down. The model was then repaired, and 25,900 applications of two-fifths its breaking weight, and afterwards nearly 3,000,000 applications of one-third its breaking weight were made, it is said, without injury.

The application of iron to bridges, especially to those of large span, necessarily requires the most careful consideration in apportioning the strains, since every pound of metal not brought into effective action is so much dead weight, or useless load, being not only misapplied of itself, but requiring additional material to support it.

The practice among American engineers is very uniform. The factors of safety are almost invariably as follows: For parts subject to constant strain, six; and for parts subject only to occasional strains, four. These figures are factors of *ultimate* strength. The margin of safety has, in all cases, been ample so far as we can learn.

TRACTION ENGINES.

From "The Engineer."

Although the very first carriage ever propelled by steam was constructed years before railways were thought of, and, as a natural consequence, made the first tottering essay at mechanical locomotion on a highway, common roads still remain almost unavailable as a means to locomotion by engine power. A very few years since—a dozen, let us say—an idea sprang into existence that every portable agricultural engine might be, ought to be, and would be made self-propelling, while very large numbers of engines, specially designed, not to drive threshing machines or ploughs, but to haul loads, would be built. Gentlemen like Bray and poor Boydell fostered this idea, and threatened the railways. The railway companies paid not the least attention to the matter. It could be easily proved, they thought, that steam on the common road would never beat steam on rails, and in a sense—and a large sense, too—it is certain that railway companies and their engineers were right in this conviction. The rage for traction and self-propelling engines died out. At this moment it is probable that a smaller number of traction engines is in use than at any other period within the last six or eight years. The number of self-propelling engines—that is to say, of engines intended to take themselves and a plough or threshing machine from farm to farm—is probably much greater, but it must be remembered that from these latter machines railway companies have nothing either to hope or fear; they add not at all to facilities for locomotion, and their abundance or scarcity does not affect the great problem of transporting heavy goods or materials on common highways by using steam instead of horses. With limited exceptions, the traction-engine system has proved a complete failure. It is true that hundreds of traction engines have been built here and elsewhere, and sent to all parts of the world and put to work, and have remained at work till worn out. But this fact is of the smallest importance. If the traction engine had been a success, it would have done for horse haulage what the locomotive did for the stage coach. Instead of hundreds of traction engines we should have built, sent away, and put to work, thousands.

No one disputes that steam might be employed with great success on common roads as means of cheapening the transport of heavy goods or materials of all kinds, such as corn, timber, coal, ores, lime, bricks, and such like; but neither does any one dispute, so far as we are aware, that steam is not so employed either here or abroad, except in a very small and insignificant way, with success. When it can be predicated by intelligent engineers that a given machine ought to succeed, while it can be proved that it does not succeed, a problem is presented, which we, as technical journalists, are bound to consider, and if possible to solve. Let us attempt, then, to solve this question, bringing, we may add, without overstepping the bounds of editorial modesty, at least a little practical experience in traction engines to bear on the matter in hand.

It is very commonly urged that traction engines are not more commonly used because the law concerning them is harsh, repressive, and almost prohibitory. Now even if we granted this statement to be a statement of facts—and we do not—it proves very little for the traction engine builder. It is true that the law prohibits a greater speed than four miles an hour, and orders that each engine shall be preceded when on the road by a man with a red flag, etc. But, in the first place, this rule is not very oppressive, and, in the second, engineers have only themselves to thank for its existence. Traction engines, as they are, are unutterably hideous, astoundingly noisy, and to the last degree offensive in the matter of smoke—not only to horses, but to men. If it could be proved that these conditions are inseparable from the system, then we should have small hopes indeed of the ultimate success of steam on the highway. We believe, however, that the ugliness, noise, smoke, and general nuisance, all result from the great fact that those who have built traction engines up to the present moment have not realized the importance of getting rid of the specified objections—or, realising it, have been unable to design engines of better construction. A glance at the contents of any agricultural show will prove that the ruling principle guiding the makers of traction engines is to take the ordinary portable engine and adapt it to drive a pair of road wheels. As a result, we have an engine without springs and with all the gearing exposed to the broad glare of day, thumping, and clanking, and grinding, and smoking along our highways. The thing is a nuisance, an unmitigated nuisance, and it is folly to deny the fact. Worse than this, the nuisance is continually getting not only its owners but itself into trouble by breaking down; and all this because a machine specially designed for one purpose is applied to another.

Without engravings it would be impossible to show what a traction engine should be. Perhaps our portfolio of working drawings may yet include one design, disposing of most, if not all, the objections concerning smoke, noise, ugliness, and breakdowns. For the present we shall content ourselves with indicating a few of its features. We have stated that traction engines as they exist are a nuisance, and this in itself is one very sufficient reason why steam on the common road is not a success; but one or two others of even more importance remain to be considered. The first is, that, all things considered, traction engines do not compare favorably as regards the cost of the work done with horses; the second is, that they consume large quantities of water, which cannot always be had, and that even when it can be had, much time is wasted in taking it in. Four miles an hour running time, in all cases becomes three miles an hour including stops to take in water. We have now put before our readers, in one way or another, most of the objections to traction engines. Let us see how they are to be got over.

In the first place, a radical change must be made in the arrangement of the entire machine as compared with those now in use. Instead of the portable engine, we must take the railway locomotive as our model. The first point to be settled is the construction of the machine regarded as a carriage. As the road to be traversed is rough, and machinery does not like rough roads, the two must be kept apart as far as possible. Therefore instead of mounting a boiler half full of water on rigid wheels without the interposition of springs, and a heavy, quick-running engine and fly wheel on top of the boiler, we must provide a rectrangular frame of iron or of oak between iron plates. The frame must be supported on wheels—preferably of wood—through the intervention, not only of springs, but of perfectly efficient and elastic springs, with india-rubber buffing-pieces to take up the last trace of jar and vibration. Next we have to provide a crank shaft running in brasses fixed in wrought iron cheeks—no cast iron except that in the cylinders and a little in the gearing should be allowed in a traction engine—which crank shaft must be driven by a pair of pistons, in order to get rid almost or altogether of the fly wheel—and unnecessary and objectionable excrescence, which should have no more place on a traction engine than it has on a locomotive.

The next step is to provide means by which the crank shaft when revolving will cause the hinder wheels to revolve also. For this there is nothing like a chain, only the chain must not be run too fast, must have plenty of bearing surface, and must admit of being tightened when it gets slack. Various modification of the chain may be used, but we will not stop to consider these just now. If the engine is intended to run at slow speed with heavy loads, intermediate gear must be employed. On the crank shaft a pinion is to be placed gearing into a spur wheel about 3 to 1, and the shaft of this spur wheel—lying across the frames in the rear of the crank shaft—will carry a small chain wheel, while a large chain wheel will be fixed to the boss of one of the road wheels, either or both of which will be fixed at pleasure to the axle. When moderate speeds are allowable the chain pinion may be fixed direct on the crank shaft, which may make nine revolutions for one of the road wheels. If these last are a little under 6 ft. in diameter they will revolve about 288 times per mile, or, at five miles an hour, twenty-four times per minute, which gives 216 revolutions per minute for the engines, the cylinders of which should not be too small in diameter. Ordinarily, steam will be worked expansively in them. By admitting it full stroke, sufficient power may be developed to get the engine up a steep hill or out of a difficulty, at least such a difficulty as will be encountered on a good road—and five-mile an hour engines should not work except on good roads.

The character of the boiler and the position of the cylinders remain to be settled. In any case the crank shaft should be placed as nearly as possible on a level with the road axle—why, we shall not stop to explain. If the locomotive type of boiler be used, then the clinders go into the smoke box; but under certain circumstances it will be found best to use a vertical boiler placed at one end of the frame, while a water tank is placed at the other, the cylinders being placed vertically between. The use of vertical cylinders will not induce much jump, if any, in a heavy engine; and by adopting the vertical instead of the horizontal arrangement one great difficulty is disposed of. The cylinders and engine can be put near the ground and yet remain accessible and out of the dirt. All the machinery must be boxed-up out of sight.

We have yet to get rid of the waste steam and the smoke. By taking the exhaust through a superheating pipe in the furnace the waste steam may be rendered invisible, and the noise may be completely obviated by discharging from the cylinders into a receiver. As regards smoke, that must be got rid of by the use of coke.* We are unacquainted with any other expedient which will *effectually* prevent the evolution of smoke from the small furnace of a traction engine. Its compulsory use would be no great hardship.

* Or in America by the use of anthracite.

THE SPECTROSCOPE.

From the "American Exchange and Review."

That ordinary or white light may be decomposed by refraction into what are commonly known as the "colors of the rainbow," is a familiar fact. Every transparent substance of greater density than that of air, and bounded by surfaces inclined to one another, gives evidence of this dispersion, as the separation into color is technically called. We see it in the drops that fall from the clouds, in the flashing hues of the diamond, and in the pendants of chandeliers; but it is most conveniently and perfectly exhibited by what is called a prism—a piece of glass having two surfaces greatly inclined to each other. Light, after passing through any of these dispersive media, is no longer of simple and uniform whiteness; it is transformed into a series of the most vivid and delicate tints, melting into each other by an insensible gradation, from a dark heavy red, through brilliant orange, green, and blue, to a deep and tender violet. We are not now concerned with the inquiry, how this diversity of hue is universally found where refraction, or bending of the rays of light, takes place; and whether color is so connected with refraction that every progressive degree of refraction produces its own tint, in which case each hue would be simple and independent; or whether some, at least, of the colors may not be of composite character. The question now seems to lie between a superimposition of three bands of the colors recognized as primaries in painting—red, yellow and blue—equal in extent, but very unequal in intensity in different parts of their length—and a continuous series of literally innumerable hues, each equally elementary and self-subsistent, and each passing, without the least overlapping, into its neighbors on either side by the most delicate and imperceptible modification.

The spectroscope, an instrument invented by Frauenhofer, is destined to take rank with the telescope and the microscope as a revealer of mysteries. Its structure is sufficiently simple, comprising, as its essential parts (for the details are subject to much variation), a slit of adjustable narrowness between two metallic plates, to eliminate the overlapping of the spectra; a prism, or rather, in order to obtain a wider dispersion, a combination of prisms, to decompose the admitted but straightened ray; and a small telescope, the intention of which is to magnify the spectrum thus formed, and rendered sufficiently pure to exhibit its interior arrangement, so as to unfold more effectually its complexity. The investigation conducted by means of this beautiful apparatus is known as spectrum analysis, and it is equally applicable to every kind and degree of light, provided it retains sufficient intensity, after this unsparing reduction and expansion, to form a distinct impression upon the eye.

With the light given out by the terrestrial elements raised to incandescence, a vivid spectrum at once streams from the prism. Any solid element thus ignited affords a band of brilliant colors, but without the crossing of a single dark line. Urge it until it flows down in fusion, still the unbroken spectrum remains; but force on the heat till the material rises into a glowing vapor, and the scene is changed. At once the continuous spectrum, the uninterrupted stream of color, common to every ignited solid or fluid element, is converted into a succession of transverse lines, brilliantly and variously tinted according to their place in the spectrum, extremely narrow fragments, as it were, of the continuous spectrum, and separated by intervals, more or less wide, of darkness—gaps where that spectrum has totally disappeared. This is strange, and in its first impression strangely irregular; but further examination shows us a yet stranger regularity. There is no rule as to the thickness or position or grouping of the bright lines, but we shall find that every chemical element, whatever its nature, has, when in a state of vapor, a system of lines of its own, and so peculiarly appropriate to itself that the appearance or non-appearance of those lines is an infallible criterion of the presence or absence of that element.

The spectrum, as the band of varied hues is called, when obtained direct from the sun by refraction—whether naturally, as through the bow set in the cloud, or the rain drops pendant on the leaves, or artificially, as through a prism of glass or other suitable material—exhibits nothing more than a succession of brilliant tints passing gradually from red of various qualities, through yellow and green, to blue, deepening into violet. But a little consideration will show us that these colors, however compounded in their own nature. cannot under these circumstances be regarded as absolutely simple and pure. They would be so if the sun were a point; but the breadth of its surface, or, in astronomical language, disc, prevents the complete analysis of its light; for every portion of this disc, from the one side to the other, in whatever direction the refraction may have been effected, has been contributing its own share of light to every portion of the spectrum, so that the latter, instead of being a simple decomposition of one pencil of light issuing from one point, is an overlapping, to a certain small but not inconsiderable degree, of innumerable spectra from an infinite number of luminous points, producing a confusion, the limit of which is, of course, the apparent breadth of the source of light. Within that confusion, that crowding together and intermixture of neighboring tints, some mystery may lie concealed, and fortunately the means are ready to our hand to explain it. We can thin out the crowd to a simple rank by reducing the visible breadth of the sun to a single point. Or, better still, since the tints are mingled and confused only in one direction, that of the refraction, we may, by means of a slit which can be adjusted to any amount of opening, narrow the sun's disc to a mere transverse line of light, which, preserving the full breadth of the spectrum in its own direction, and giving us, as it were, a ribbon dyed in transverse bands instead of the single parti-colored thread which would issue from one point of light, makes the phenomenon conspicuous enough for study, while the confusion arising from overlapping is removed. Thus formed from a single narrow transverse streak of light, the spectrum is no longer a continuous band; its colors remain as they were, but it is full of interruptions; it is crossed in innumerable places—the best instruments show upwards of 2,000—by dark lines, some much broader and more conspicuous than others, but all of hair-like minuteness, and in most irregular arrangement and fortuitous grouping.

The spectrum of the sun is discontinuous, with hair-breadth tracks of darkness. The spectra of the terrestrial elements are also discontinuous, but with hair-breadth lines of light. The one seems of a class which is the reverse of the other; but this apparent contrariety will lead to further thought and further investigation.

The discovery of the true meaning of the solar spectrum, in 1859, was the commencement of a long series of discoveries in solar physics. It had long been noticed that the rainbow-colored streak of light which forms the solar spectrum is crossed by a multitude of dark lines. Some of these lines are well marked, others faint; at one place many are crowded together, at others there are scarcely any; but at all times the same lines make their appearance. For a long time this phenomenon remained without explanation, as also did the correlative phenomenon that the spectra of incandescent vapors consist, not of a rainbow-colored streak, but of a definite number of bright lines. But Kirchhoff, in 1859, made the important discovery which forms the basis of spectroscopic analysis. He found that the dark lines in the solar spectrum correspond to the bright lines of the spectra of incandescent vapors. For example, the double orange line which forms the spectrum of sodium vapor occupies exactly the same place as a well-marked double dark line which appears in the orange part of the solar spectrum; and so with many other similar lines or sets of lines. In fact, he demonstrated that the presence of dark lines in the solar spectrum indicates that the light of the sun shines through a vaporous envelope, and that the vapors which form this envelope are the same which, in an incandescent state in the chemist's laboratory, produce the bright-line spectra corresponding to certain of the solar dark lines.

To sum up in a few words those principles of spectroscopic analysis which are our chief guide in solar researches: An incandescent solid or liquid gives a continuous rainbow-colored spectrum; an incandescent gas gives a spectrum of colored lines; and an incandescent solid or liquid shining through a vaporous envelope gives a rainbow-colored spectrum crossed by dark lines, and these lines have the same position as the bright lines which belong to the spectra of the vapors which form the envelope.

THE PARIS STEAM ROAD ROLLER.

From a paper read before the Institute of Mechanical Engineers, by Mons. M. E. Gellaret.

This roller consists of a locomotive engine carried entirely upon two large cast-iron rollers of equal size, which are both driven by the engine, the course of the machine being controlled by a special arrangement for changing the direction of the roller axles. The result is that the whole of the weight of the machine is made available both for the rolling of the road and for propelling the machine. The engine is capable of being readily started in either direction without any slipping, and can easily round very sharp curves. This machine is the only one which allows all the weight to be made available for adhesion in driving—an indispensable requisite for a really complete rolling machine—none of the weight being dragged; and machines having only one axle driving are liable to slip at starting, causing damage to the road surface to be rolled, and wasting power. Also, the direction of the motion, whether forwards or backwards, being entirely indifferent, is another essential point for rolling roads. By a special mechanical arrangement the communication of the driving power is maintained direct to both the rollers, however much they may be inclined to each other when traversing a curve; this driving apparatus is made very strong and durable, and it has been found completely successful in work. The weight of the machine is equally divided on the two rollers, and the adhesion for driving is so great that these machines have worked up hills with a gradient of 1 in $12\frac{1}{2}$. They are guided with the greatest facility and certainty on the most difficult and winding roads, by the axles of the rollers being made to converge to the centre of the circle which is being traversed. These machines have now been in regular use in Paris for four years, and the results of their working have so thoroughly established their durability and economy that they are used for the whole of the roads in that city and the suburbs. The machine has a longitudinal wrought-iron frame, like a locomotive engine, with cross bearers to carry the boiler, and a water tank at the back of the footplate. The two large carrying rollers are 3 ft. 10 in. in diameter, and 4 ft. 7 in. in length. They are cast-iron cylinders of $1\frac{1}{2}$ in. thickness, with intermediate strengthening ribs and internal flanges at the ends, to which wrought-iron plate covers are fixed. These close the two ends of the rollers, and have cast-iron bosses in their centres for bearing on the axles. The axles are stationary, and the rollers revolve round them with bearings extending the whole length of the roller, and consisting simply of a cast-iron cylinder, with a continuous bearing on the axle, and furnished with a spiral groove for lubrication. The rollers in the first of these machines were made with separate wrought-iron wheel centres, upon which was riveted a cylinder of boiler plate; but this make was abandoned in consequence of the frequent failure of rivets, which were sheared off by the stretching of the cylindrical plate from rolling out. The present make of cast-iron rollers, heavier than the original wrought-iron ones, but less expensive in make, has proved very satisfactory, and they have done a large amount of work without any expense for repairs, some of them having run as much as 3,000 miles without any sign of cracking or splitting. The first cast-iron rollers were made quite cylindrical; but it was found that the surface became worn down more at the end next the chain-wheel than at the other end; and to meet this irregular wear the rollers have since been cast slightly conical, with the larger end towards the chain-wheel, so that when half worn down they may become truly parallel. One end of each roller has a manhole in it, giving access to the interior for oiling the bearings. There are two sizes of these machines used in Paris—one weighing 15 tons and the other 30 tons in average working order. The smaller one has rollers 3 ft. 11 in. in diameter and 4 ft. 7 in. in length; the rollers in the larger one being 4 ft. 9 in. in diameter, and 6 ft. length. These machines were adopted for rolling the roads in Paris, in consequence of the satisfactory results of a series of experiments made with them under the direction of M. Michal, director of the municipal service, by M. Homberg, engineer-in-chief of the public roads of Paris. The machines are hired at a fixed charge, which is regulated by the weight of the machine and the distance run in work; the rate being per ton per mile of the machine, 7d. by day and 8d. by night. This rate includes all expenses of wages, coals, and materials for working and repairs, excepting the supply of water, which is furnished by the municipal authorities. The work of each machine is measured by a self-acting counter, indicating the distance traveled, measured at the mean diameter of wear of the rollers; the measurement of distance being taken only during the actual time of rolling, with an allowance added of three miles for traveling to and from the place of work. The work is, as a general rule, done in the night within the city, the portion of road repaired during a night being completely finished by the morning ready for traffic. The speed of working is from $1\frac{1}{2}$ to $2\frac{1}{2}$ miles per hour, being limited to the latter amount by the public regulations. The usual practice in repairs is to lay down a layer of broken stone about $2\frac{1}{2}$ in. thick at the sides of the road, and 6 in. thick in the middle; the surface of the road being generally picked up previously. The rolling engine commences work at the opposite sides of the road; alternately traveling backwards and forwards over a length of about 100 yards, and working its way gradually to the middle of the road, when it proceeds to roll another similar length. The layer of broken stones is watered from the street mains, and binding material, consisting of road scrapings, is put on before the rolling. There is not the slightest difficulty experienced in reversing the motion of the rolling engines, and they start in either direction without any slip whatever, and the broken stone is regularly rolled down without getting pushed up or driven before the rollers. The engines start with great facility, even on a considerable incline, and they turn easily in a circle of only 13 yards radius. In making new roads the broken stone is usually laid down in a single layer of 10 to 12 in. in thickness, and this thickness of material can be satisfactorily rolled. The total distance traveled per day of ten working hours by one engine is usually from 15 to 20 miles. In working, two men are employed for the smaller engines—an engineman and a steersman, and for the larger engines a fireman in addition, for the purpose of oiling upon the road without stopping the engine. The mean power developed by the larger engines is about twenty horse power. It is often below that amount, and then sometimes rises to thirty or even thirty-five horse power. The engines keep well in order, and run from 1200 to 1800 miles before requiring any important repairs. They are made very strong; the axles, chains, pinions, and working gear being made of steel, and the engines of the quality of best locomotive work. They are consequently expected to keep at work fully ten years. In reference to the relative cost of rolling roads by the steam roller or by horse power, the following facts may be taken as a comparison of the prices per ton per mile by each plan. The result of numerous data shows the cost of horse rolling in Paris (including horse keep, drivers, and oiling) to be 11d. per ton per mile, or about $11\frac{3}{4}$d. including cost of repairs. The addition of interest of capital and depreciation would raise the total cost to about 14d. per ton per mile. On the other hand, for the steam rolling the actual payment is only half that amount, or 7d. per ton per mile, including the contractor's profit; so that there is a great economy as regards cost of power in the steam roller. The advantages of the steam roller over those drawn by horses are, economy in the cost of the work, rapidity of execution, and greater perfection in the work done; the durability of the road surface being found to be at least doubled where the steam rolling has been well done, as compared with roads not so rolled.

On the Influence of Severe Cold on Metallic Tin.—Fritzsche, of St. Petersburg, communicated to the Paris Academy the interesting fact that during the severe cold of last winter, in St. Petersburg, large blocks of Banca tin became crystalline through the whole of their mass. They now contain in their interior, hollow spaces of up to 100 cubic centimeters. The walls of these hollow spaces are smooth and shiny. The other parts of the tin which have been transformed partly into small crystalline grains, partly into brittle pieces of various sizes, have a dull appearance, caused probably by superficial oxydation.—(*Compt. Rend.*, t. 67, p. 1106.)

LIGHT VS. HEAVY LOCOMOTIVES.

ROLLING STOCK ON THE METROPOLITAN RAILWAY.

From "The Engineer."

Those who are interested in the often-discussed merits of light *versus* heavy rolling stock, will find just now much deserving of their attention in the working of the Metropolitan Railway. They may there see some of the lightest tank engines and carriages recently used for main line traffic, working side by side with the heaviest stock ever put on any line. A very important problem, therefore, bids fair to receive a speedy solution on the Metropolitan Railway; and the solution will, unquestionably, possess every characteristic which can render it absolutely final under the prescribed conditions. In a word, a most valuable experiment is being tried on the largest scale; and the result, be it what it may, must be accepted as conclusive. The facts may be stated in a very few words, but they will be all the better for a little explanation.

The first engine designed to work the Metropolitan Underground Railway, was fitted with air pumps and an injection condenser. Its weight was something enormous, and its performance so unsatisfactory that we believe it never ran a single passenger train. The line was first practically worked by the Great Western Railway Company with broad gauge engines, having outside cylinders and six wheels, four of them being coupled. These engines did very fairly, and are now in use down the country. Next came an interregnum, when the traffic of the line was conducted by the Great Northern Railway Company with their ordinary narrow gauge mixed engines, blowing their waste steam into the tender through a temporary exhaust pipe. Meanwhile, Mr. Fowler prepared designs for new narrow gauge tank engines. These engines being specially designed to work underground, possessed not a few novel features. Twelve were built in the first instance by Messrs. Beyer and Peacock, and, as a natural consequence, the work is simply faultless. We cannot say as much for the design. It was of the utmost importance that the engines should get away quickly with their trains, yet the driving wheels are 5 ft. 6 in. in diameter, a dimension rendered inexcusable by the fact that only a moderate speed was demanded. In order to compensate for the size of the wheels, and to still retain the great tractive force, essential to rapid starting, large cylinders were of necessity adopted. We need not stop to explain how great an augmentation of weight this entailed. It was next assumed that the curves would be bad to get round with a six-wheeled engine, therefore a bogie was introduced principally because the engine was made too long to begin with. This farther increased the weight, and so, finally, Mr. Fowler produced the now well-known narrow gauge standard Metropolitan engine, weighing nominally 42 tons, but in all probability at least 45 tons loaded. This monstrous machine is employed to haul trains consisting of five not less monstrous carriages, carriages mounted on eight wheels disposed in two groups, and weighing 16 tons each. We have thus a locomotive weighing 45 tons hauling a train weighing 80 tons, carrying, when full, 20 tons of passengers or so, at a speed of 25 miles an hour, over the best permanent way ever laid down: gross load, 155 tons; paying load, 20 tons, or less than half that of the engine alone. There are no exceptionably heavy inclines to be surmounted, and the bad curves are few in number, and at the worst do no great harm, because the speed at which they are traversed, as at King's Cross, for example, is low. We fancy that every unprejudiced engineer, with these facts before him, will admit that Mr. Fowler's engines are not the best that can be designed for the intended purpose, and that, all things considered, they are apparently very much underworked. The driving wheels are much too large, the machine too long, and, above and beyond all, the enormous weight of the engine constitutes a grievous defect. There is no denying the fact that the standard engines play havoc with the permanent way of the Metropolitan Railway, smashing off the tables of steel rails, and grinding out the best Bessemer track, perhaps in the world, as though it were made of iron.

Mr. Fowler has gone on adding to the original stock of twelve engines with others built off the same patterns; but we find that neither the Great Northern, the Midland, nor the Great Western Companies have followed his example. The Great Western Company put on some broad gauge engines with six very small coupled wheels and inside cylinders, three or four years ago; these have been abandoned with the broad gauge. The Great Northern Company, in working steeper inclines than any which the Metropolitan engines are called on to traverse, adopted a design differing widely from Mr. Fowler's. The Great Northern engines weigh full but 33 tons. They have four coupled wheels, 16-in. cylinders, and a pair of trailing wheels mounted with Adams' radial axle boxes. These engines gave great satisfaction. Next came the Midland with a modification of Mr. Fowler's design, the engines weighing much less, however. And, lastly, we come to the rolling stock put on by the Great Western Company within the last few months, which is the very antithesis of Mr. Fowler's. Now, if the designs of the latter gentleman had been proved to be right by the results of three years' working, how is it, we may ask, that the engineers of other companies have not followed his example or endorsed his practice by adopting his typical engine and carriages? The fact that they have not, is the best possible proof that Mr. Fowler made a great mistake when he designed his standard rolling stock for the underground railway.

We do not propose here to say anything more of the methods adopted by the Midland and Great Northern Railway in working their metropolitan traffic. We shall confine our attention to the new engines and carriages used by the Great Western Railway Company in working their local traffic between Windsor, Ealing, &c., and Moorgate street, since the abandonment of the broad gauge between Bishop's road and the City. The engines resemble those used by the Midland Company in working their metropolitan traffic, but they are rather smaller, and certainly more elegant. They have flush boilers with a very small central dome, a pair of side tanks, and a condensing arrangement very similar to that used in the standard engines. They have six wheels, four of them being coupled, and inside cylinders. These engines weigh full, one with another, as nearly as possible $32\frac{1}{2}$ tons, or from 11 to 12 tons less than Mr. Fowler's engines. The average train drawn consists of six light carriages, but this in no way represents the capacity of the engines. In the early part of the day the trains are much longer; and on several occasions fourteen carriages have been taken from Windsor to Paddington, a distance of about eighteen miles, in a little over twenty minutes. We have carefully timed these engines when getting away with their trains, and found them to be quite as expeditious as Mr. Fowler's engines, perhaps a little more so. In every respect their performance is most satisfactory. We have, then, in few words, the Great Western Railway Company doing the same work that the Metropolitan Railway Company are doing, with a dead weight less at least by 25 tons per train, if we assume ten of the Great Western carriages to carry only as many as five of the Metropolitan carriages.

It remains, of course, to be seen how the Great Western light stock will work out in continuous practice; so far, it leaves nothing to be desired. The carriages, though small, are lofty and comfortable; they are not as yet disfigured by hideous advertisements; perfect time is kept, and a carriage or two being easily added or taken off, as may be necessary, the trains are, as a rule, fairly filled, without being overcrowded. If Mr. Fowler's method of working metropolitan traffic can be made to pay—and it is—then much more should the Great Western system pay. In the case of the engines alone, the cost of transmitting each ton of dead weight from place to place cannot be much less than 2d. per ton per mile. Taking the very moderate estimate of 20,000 miles as the distance run each year by each engine, we have a saving on 12 tons less in the Great Western engines, as compared with the standard Metropolitan engines, of £166 per engine per annum, or for the Metropolitan Railway Company, with 36 engines, a saving of, in round numbers, £6,000 per annum; while, if we regard the smaller weight of the carriages, and the increased durability of the permanent way, due to the use of light rolling-stock instead of heavy, we shall find that the saving may possibly reach double the sum we have named.

CAST-IRON FORTS.

From "Engineering."

In these days of Shoeburyness trials, when almost every conceivable combination of iron and steel capable of forming a target has been subjected to hammering by shot and shell, with more or less satisfactory or unsatisfactory results, it is something to come across the proposal of a really novel, and at the same time promising, system of fort construction. We have had shields formed entirely of wrought iron, shields of iron with wooden backing, shields of iron and steel, granite casemates with iron shields, and a host of other devices, and now we have Mr. Thomas R. Crampton's proposal to make forts of cast iron. Not a very promising material some of our readers will say; and we must own that except it be employed in the way Mr. Crampton proposes, they are right. The proposal to use cast iron as a material for constructing shields or defences is not new, and Mr. Crampton lays no claim to it; but what he does claim is the plan of constructing forts by casting them *in situ*, either in one single piece or in blocks of large size, each weighing not less than 200 tons or so. Forts thus constructed would afford very different resisting powers to defences built of cast-iron blocks weighing three or four tons each, such as have been in some cases proposed; and although we have no data from which we could calculate what the resisting power of such massive blocks as Mr. Crampton proposes to use would be, we are, we think, justified in stating that the system is worthy of a trial.

That there would be no great practical difficulty in constructing such forts is certain. The process would be merely an extension of that which has been so successfully carried out by Mr. Ireland in a number of instances, when large anvil blocks have had to be cast. All that would be requisite would be to prepare the necessary foundations, and construct *in situ* a mould of the required form, this mould being either made of brickwork, or of a combination of brickwork and iron framing, according to the circumstances of the case. Around the mould would be arranged, in convenient positions, a series of cupola furnaces, the number of these furnaces being regulated by the size of the casting to be produced and the time allowed for completing the operation. Mr. Ireland has, as we have said, produced a number of large castings by a similar method, and about eighteen months ago (*vide* page 496 of our fourth volume) we described the casting in this way of an anvil block weighing 210 tons at the Bolton Iron and Steel Works. The metal for this block was run from two cupolas in $8\frac{3}{4}$ hours actual working time, and the casting proved perfectly successful. Judging from the experience already gained, there appears to be practically no limit to the size of the castings which can be produced on this system, and we feel certain that Mr. Crampton would have no difficulty in casting his forts, as he proposes, in solid blocks, weighing 5,000 tons or so, if occasion should require it.

We have said that we have no data as to the resistance to shot afforded by cast iron in large masses; but we are inclined to think that it would be satisfactory. Mr. Crampton, however, does not confine his plan to the application of cast iron alone; but he states that the metal may be strengthened by melting up scrap iron with it, or in some cases the castings may be formed of steel or iron produced by the Bessemer process. Whether it would be possible to apply the Bessemer process to the satisfactory production of such gigantic masses we cannot say, but we have no doubt about the possibility of producing them in plain cast or toughened cast iron. In the case of the cast-iron forts being of such form as to require portholes, Mr. Crampton proposes to guard each opening by the insertion in the casting of a massive block of wrought iron or steel of suitable form.

As for the expense of constructing such forts as we have above described, Mr. Crampton estimates that a cast-iron structure might be made six or seven times the thickness of a built-up wrought-iron structure of the same total cost; and considering the high price of heavy wrought-iron armor plates, we do not think that this estimate is an unreasonable one. All events, we think that our government authorities might do many worse things than test the effect of shot and shell on a 200-ton block of cast iron.

LIQUID FUEL IN METALLURGY.

From the "Mechanics' Magazine."

The advantages of liquid fuel, when properly used, over coal, for steam purposes, have long since been fully demonstrated, and they stand unquestioned. Hitherto, the endeavors to utilize mineral oils have been chiefly confined to the furnaces of boilers; but now we have another eminently successful application of the oil furnace to metallurgical purposes. Our readers can hardly have forgotten the successful trip of the "Retriever," a steam ship of 500 tons burden, which was fitted up on the system of oil furnace invented by Mr. Dorsett, of London.* This system consists in burning in the furnace the vapor of creosote, which is produced in an auxiliary boiler. Having established the success of the principle in one direction, Mr. Dorsett conceived the idea of utilizing it in another—that of heating iron plates for bending. The idea was first put into execution about four months since, when Mr. Dorsett obtained permission to apply his system of burning liquid

* Van Nostrand's Magazine, No. 1, p. 57.

fuel to a plate-burning furnace in Woolwich Dockyard. This was for plates of the ordinary thicknesses used in iron shipbuilding, and the results were so satisfactory that the authorities directed the principle to be applied to an ordinary plate-bending furnace and to an armor-plate furnace in Chatham Dockyard. It is to the latter of these we wish to direct special attention, as being a great triumph of the Dorsett principle of burning liquid fuel.

Under ordinary circumstances, the armor-plate bending furnace is lighted from four to five hours before the plate is placed in it. The time occupied in heating the plate for bending depends upon its thickness—one hour per inch of thickness being allowed. Taking, then, a 6-inch plate—as upon the present occasion—we get from ten to eleven hours from the time of starting before the plate is ready for bending. Let us now see what the liquid fuel will do. Upon our visit to Chatham, the cold furnace was lighted, and after an hour was deemed sufficiently heated. A 6-inch armor-plate, 7 ft. 6 in. long by 3 ft. wide, was then consigned to the furnace, and after an hour and a-half was drawn out thoroughly heated and ready for bending. Thus, in two hours and a-half we have the work of ten or eleven hours completely and satisfactorily performed. Nor is this all; the advantages of the system do not stop here. The plate was remarkably free from scale, which can only be accounted for by the absence of the deteriorating influence of the products of combustion in the ordinary furnace. Another valuable result arises from this same cause; thinner plates, when heated by liquid fuel and bent double, show no signs of cracking, as they usually do when they have been heated in the coal furnace. This important feature is reckoned to save ten shillings per ton on the metal, which amount it would lose in value by deterioration under the ordinary method of treatment. The vaporized creosote is supplied to the furnace under notice from the generator by six jets, which are led in through small openings, by which means also just a sufficient quantity of atmospheric air is admitted to support combustion. This method of supplying the heat also offers another advantage; it can be applied to the whole or any portion of the plate. Thus, if a plate requires to be bent at one end only, then the heat is directed to that part. Further, the rate at which the metal is heated can be regulated to a nicety by either increasing or diminishing the number of jets. The consumption of oil at Chatham is 108 gallons per furnace per day.

Close beside the armor-plate furnace is another one for heating thinner plates, and which has been regularly at work for some time past. It is heated by four jets, and is supplied from the same generator as the larger one, and which is placed between the two. On the occasion of our visit some half-inch plates were being heated and bent to various templates. The average time occupied in heating was seven minutes; with the ordinary furnace it takes from twelve to fifteen minutes for each plate. As already stated, the heating of the 6-inch plate was only experimental and preparatory to a regular course of practical work which is about to commence. But it was an eminently successful experiment, and, moreover, was not the first made in the same furnace. The plate in question had been through the same process three times previously, although its clean, smooth surface would not have led to that supposition, for it had the appearance of having had nothing done to it since it left the rolls. The future work of the furnace will consist in heating the armor-plates for bending for the "Sultan," a vessel of 5,226 tons burden, now constructing. In this furnace we have another practical evidence of the value of liquid fuel when utilized in the form of vapor. In its working we have some of the most remarkable and unlooked-for results, which, while they fully satisfy us for the present, only lead us to expect further and even more important improvements in the application of the system.

The Bessemer Steel Works at Troy.—The two-ton plant of Messrs. John A. Griswold & Co. is in constant operation, producing some 300 tons of rail ingots per month. The walls and machinery of the new five-ton plant (to replace that destroyed by fire in October last) are nearly completed, upon an enlarged plan. The roofs, furnaces and smaller machinery, are yet to be placed. The new blowing engine, the largest in this country, is nearly ready to run. This company are prepared to take orders for rails for spring delivery, and will be able to execute them upon the completion of the new plant this fall, at the rate of 1,800 to 2,000 tons per month. They are also prepared to furnish rolled bars and shapes in steel, having erected a heavy mill for this special purpose.

ON RIVETS AND RIVETING.

BY MARTIN BALCKE.

Translated for Van Nostrand's Magazine from Polyt. Centralblatt.

The following remarks do not refer to riveting for the purpose of merely uniting two parts of machinery or two sheets of iron, but they apply to rivetings which require a higher degree of strength and solidity, as, for instance, for boilers and working parts of machines. It is a general rule for all constructions, especially for those in iron, to distribute the strain which has to be withstood by a certain part of a machine, as evenly as possible over the solid mass of the said part. This rule is also very important in the use and arrangement of rivets. The simplest and safest way to carry out this rule is to calculate directly the areas of the working sections, and to see that the strain which acts on any part of a section, does not exceed certain limits generally conceded to the respective materials. This is the way, also to avoid the use of empirical formulæ, the most important coefficients of which are always dictated by the personal opinions and notions of their authors.

The force necessary to tear a wrought iron bar of a certain section, is so nearly equal to that required for cutting or shearing the bar, that both may be considered as equal in calculations, for practical purposes. The limit of elasticity of soft wrought iron, as generally used for rivets, is at a pressure of about 18,000 lb. on the square inch. With boilers the strain of tension per square inch of section of the material, ought not to reach 9,000 lb.; because continued heating and long use weakens the material considerably. In the construction of stationary boilers, one square inch of section, taken through the riveting, ought generally not to be strained above 12,000 lb. But if a riveted part of a machine has to sustain a strain acting alternately in two different and opposite directions, this strain should never exceed 2,000 lb. per square inch of section.

If a quite uniform distribution of the strain over all the sections cannot practically be obtained, at least the tension of the sections which are exposed to the highest strains ought to be kept within the above-mentioned limits.

The shape of the head of a rivet is dependent on the kind of strain to which the rivet is subjected. This strain can have the tendency of tearing or of shearing the rivet, or of both simultaneously. If a rivet has to withstand a tearing strain, the height of its head must be such that the cylindrical surface which would make its appearance when the head of the rivet would be stripped off, is equal to the area of a cross-section through the rivet. If we denote the height of the head by the letter h, we obtain the equation:

$$2r\,\pi \times h = r^2\,\pi,$$

which gives us—

$$h = \frac{r}{2};$$

that is, the height of the head has to be one-half of the radius, or one-fourth of the diameter of the rivet.

Practical experiments on the strength of rivets have come to the same result, and have besides shown very distinctly that the rivet-holes should never have sharp edges, and that the head of a rivet ought to be connected with the shaft by a conical part. Whenever this part is omitted, and when, consequently, the rivets have sharp corners below their heads and the rivet-holes sharp edges, the rivets break close to the head, when subjected to a strain of tension and when the heads are strong enough not to be stripped off. When, on the contrary, the rivets have a conical connecting part between their heads and shafts, they extend considerably before they break, and the rupture finally occurs in the middle of the shafts. All experiments have given this result without exception.

Rivets subjected to a shearing strain only, would theoretically not require any head at all. But it is good, also, in this case to make the heads of the rivets as high as above determined, because generally a close contact of the riveted parts is desirable, and because the rivets, being set in red-hot, have to resist the strain of tension produced by their contraction in cooling.

If the heads of rivets have to be countersunk, their best shape is that of a truncated cone, the angle at the point of which cone would be of 75 deg.

The sectional area of the shaft of a rivet, expressed in square inches, is found by dividing the actual and total strain on the rivet, by the strain practically admissible on the square inch of the respective material.

We will now examine the riveting of simple round boilers. We designate by D the diameter of the boiler, by P the steam pressure per square inch, by t the distance between the rivets, by p the shearing strain on every rivet in the length-row. Thus the strain to which the boiler is exposed on every rivet-distance of its length, is expressed by $D \times t \times P$, and as this strain is divided on the two opposite sides of the boiler, we obtain the formula for the shearing strain on a rivet:

$$p = \frac{D \times t \times P}{2}.$$

The strain on a rivet-distance of the rows round the boiler, is measured by a triangle whose base would be the rivet-distance, and whose height the radius of the boiler. Consequently the strain on every rivet of the rows round the boiler is expressed by the formula—

$$p = \frac{D \times t \times P}{4}.$$

Now, to obtain an even distribution of the total pressure in the boiler over all its sections, the sectional area of a rivet has to be equal to the sectional area of the plate between two rivet-holes, and equal also to the double area of a section through the plate, from a rivet-hole to the edge. If we call a the thickness of the plate, d the diameter, and q the sectional area of a rivet, we obtain the formula—

$$q = (t - d) \,.a, \text{ or } t = \frac{9}{a} + d,$$

from which we conclude that the rivet-distance is dependent on the diameter of the rivets, and, reciprocally, the diameter on the distance. To determine these, it is necessary to take into consideration the possibility of making and keeping the boiler tight, which possibility depends principally on the relation between the thickness of the plate and the rivet-distance. Let us consider a special case to explain this more fully. We suppose a simple cylindrical boiler to have a diameter $D = 42$ in.; the thickness of the plate, $a = 0.3$ in.; the excess of the steam pressure over the atmospheric pressure, $P = 42$ lb. Under these conditions the strain of tension per square inch of plate-section, taken parallel to the axis of the boiler, is—

$$\frac{D}{2} \times P \times \frac{1}{a} = \frac{21 \times 42}{0.3} = 2{,}940 \text{ lb.}$$

In taking the areas of the rivet-sections equal to those of the plate-sections contained between two rivet-holes, according to the above rule, and in calculating the following items for three different rivet-diameters, for the sake of comparison, we find—

The rivet-diameter being . .	$\frac{5}{8}$ in.	$\frac{3}{4}$ in.	$\frac{7}{8}$ in.
Area of rivet-section (sq. in.), $q=$	0.307	0.442	0.601
Distance between rivets (inches), $t = \frac{q}{a} + d$ . . . . . . $=$	1.648	2.22	2.878
Shearing strain on a rivet (lbs.), $p = \frac{D \times t \times P}{2}$ . . . . . $=$	1,453	1,959	2,538
Strain per square inch on a section through the plate, or through the rivets in the length-rows of the boiler (lbs.) $= \frac{p}{q}$ . . $=$	4,730	4,430	4,220
[The shearing strain on rivets and the strain per square inch of section in the rivet-rows *round the boiler*, are one-half of those in the length-rows.]			
The strength of the riveting compared to the strength of the simple plate $= \frac{t - d}{t}$ . . . $=$	0.62	0.66	0.70

The advantages and disadvantages of the one or other of the chosen rivet-diameters are clearly shown by these tables. The $\frac{5}{8}$ inch rivets produce a very small comparative strength of the riveting (0.62). The $\frac{7}{8}$ inch riveting has a great comparative strength; but the distance between the rivets (2.878 in.) is too large in proportion to the thickness of the plate, to allow of a good and safe tightening of the joints. The $\frac{3}{4}$ inch rivets, not showing either of the two mentioned disadvantages in a considerable degree, are evidently the best in this special case.

S.

THE STEAM CARRIAGE SYSTEM.

From "Engineering."

So much has been said and, we may add, so much has been written, at various times during the past twenty years respecting the system of working railways by steam carriages, that the subject is apt to be regarded as somewhat a threadbare one. To a certain extent it may no doubt justly be so regarded; but, we think, to a certain extent only; and we believe that the steam carriage system is yet destined to receive far more attention from railway engineers than has hitherto been vouch-safed to it. And there are several reasons why this should be the case. In the first place there can be no doubt that, in the passenger-carrying stock of the present day, the amount of dead weight bears far too great a proportion to the paying load carried; and, secondly, railway proprietors have become cognizant of this fact, and not being rendered complacent by the receipt of enormous dividends are disposed to listen fairly to the arguments of those who advocate reasonable improvements in railway working. There are moreover, other reasons besides these—as we shall point out presently—why the steam carriage system is likely to receive a more extended trial than it has yet had.

The opponents of the steam carriage system state, as one of their strongest arguments against it, that it was tried twenty years ago and failed—or at least if it did not fail utterly, that it was abandoned because it was found that it did not satisfy the requirements of railway working. That the steam carriage system *was* tried and abandoned is undeniable ; but it is well worth while to inquire more closely into the reasons for its abandonment, and see whether they would apply in the present day. It is acknowledged even by the opponents of the system—or at all events by all those whose opinion is of any great value—that the running expenses of the steam carriages formerly tried were low, that the carriages did not lack adhesion or tractive power, and that they ran steadily at high speeds ; and it is therefore not to a want of these qualifications that we are to look as a reason for their disuse. Twenty years is a very long period in the history of railways, and very many important changes have taken place since Mr. William Bridges Adams's steam carriage "Fairfield" was set to work on a branch of the Bristol and Exeter Railway, and Mr. Samuel ran the "Enfield" on the Great Eastern—then the Eastern Counties,—line. At that time the average weights of locomotives and carriages were only about two-thirds what they are now, and the proportional reduction of dead weight effected by the steam carriage system was consequently far less than it would be at the present day. The early steam carriages, also, although reflecting great credit on their designers, had one very important practical defect, this being, that the engine proper and the part affording accommodation for passengers formed a single indivisible vehicle, and, as a necessary consequence, the carriage was exposed to the dirt and smoke generally to be found in an engine shed. The early steam carriages were also wanting in flexibility, as, although they were fitted with a contrivance of Mr. Adams's for allowing a certain amount of lateral motion to one of the axles, yet they were not adapted for traversing sharp curves, and their length was necessarily limited. In recent designs, such as that of Mr. Fairlie, lately illustrated in our pages, both these defects have been remedied ; such a system of construction being adopted that the passenger carrying portion may be readily detached from that furnishing the motive power, and may thus be housed separately, whilst the double bogie system gives perfect facility for traversing curves.

Again, the whole essence of steam carriage construction lies in effecting every possible saving of dead weight ; and there are now opportunities of effecting such saving which either did not exist or were not recognised twenty years ago. The use of steel, for instance, as a constructive material, has only become common, or, indeed, possible, during the last few years ; and our steam fire-engines and the launch engines made by our leading firms of marine engineers show its usefulness in light engine construction. It is in fact by the employment of steel for boilers, connecting and piston-rods, pistons, axles, tyres, frames, and other details, that the principal reduction in the weight of steam carriages is likely to be effected. The saving of weight in each detail may doubtless be small, but the aggregate of such savings becomes something considerable. Then, again, it is not so very long since such pressures as 140 lb. or even 160 lb. per square inch now carried in many locomotive boilers were unknown in railway practice ; and, as a necessary consequence, no advantage was taken in the earlier steam carriages of the reduction in weight of boilers and cylinders, which the adoption of such pressures renders possible.

So far we have only spoken of what we may term the constructive advantages likely to be possessed by the staem carriages of the present day over those of twenty years ago ; but we must now regard the question of their introduction from an entirely different point of view. At the time when steam carriages were experimented upon, our railway system, as a whole, differed materially from that which we possess now, and still more materially from that which we are likely to possess before many years have elapsed. Twenty years ago the construction of a railway was looked upon as an important work, nowadays railways may almost be said to be manufactured, and the opening of a new line, unless it be one of exceptional importance, receives little more attention than the completion of a new street or roadway. Twenty years ago, when the total mileage of the railways of the United Kingdom was only about one-third of the present amount, branch lines formed a comparatively unimportant part of the general system, and light surface lines, serving small country towns and villages, were unheard of. At the present time, on the contrary, we have branch lines innumerable, and the question of how best to work branch line traffic has become one of the most important problems with which railway men have to deal; whilst before many years have elapsed the necessities of the country will demand the addition to our present system of hundreds of miles of light railways following as closely as possible the surface of the country traversed by them, or in many instances constructed along roads already existing—railways which it will be impossible to work economically with the engines and carriages at present in use, and which will, therefore, have to have special passenger-carrying stock designed for them.

Now, it appears to us that in the numerous branch lines of the present day, and the probably still more numerous light surface lines and tramways of the future, there is an immense field for the employment of steam carriages, which had practically no existence when those carriages were tried twenty years ago; while even on our main lines there are, as we have on previous occasions pointed out in this journal, certain circumstances under their use which would be advantageous. We believe that the advantages of steam carriages would be more universally recognised if they were not so very generally regarded as something entirely distinct from ordinary rolling stock. A steam carriage is in reality nothing more nor less than a very light train and very light engine combined, and it should be regarded as a combination of this kind, and nothing else. But, it may be said, why not employ, in place of a steam carriage, a light carriage or carriages, of the ordinary form, drawn by an engine, also of the ordinary pattern, but of light construction? At first sight it may appear that such light rolling stock would possess all the advantages of steam carriages, and obviate some of their disadvantages; and, theoretically, this is, no doubt, the case. Practically, however, the construction of very light locomotives of the ordinary pattern involves many difficulties, and we do not hesitate to affirm that no independent locomotive, capable of drawing loads of, say, 30 tons or so over lines having moderate gradients, and capable also of being run steadily at speeds of 30 or 40 miles per hour, could be constructed with such a small amount of dead weight as an engine forming part of a well-designed steam carriage. With an independent locomotive, also, the weight available for adhesion is limited to that of the engine itself; with the steam carriage the adhesion weight can be increased by imposing upon the wheels a portion of the load drawn—an important difference.

Taking, then, all the bearings of the question into consideration, it appears to us, first, that steam carriages may now be constructed which will fulfill the requirements of the traffic for which they are intended far more perfectly than those formerly tried; and, secondly, that there is at present a vast field for the employment of such carriages, both here and abroad, which did not formerly exist. Such a steam carriage, for instance, as that of Mr. Fairlie,* would work the passenger traffic on any of the Welsh lines at what, we believe, would be found to be but a small portion of the cost involved under the system at present adopted. This being the case we are glad to find that a company has been formed—under the title of the Railway Working Association—to bring, amongst other matters, steam carriages fairly before the railway public. The company which consists of but a few members, includes several engineers well known for their experience in railway making and working, as well as other engineers of acknowledged standing in their profession; and it has purchased the whole of Mr. Fairlie's patents with a view to the introduction, both here and abroad, of rolling stock constructed on that gentleman's plans, and particularly of his steam-carriage system, of which we have lately had occasion to speak in very favorable terms. It is proposed by the company to, in the first instance, place these carriages on one or more of our English lines, and maintain them for a certain percentage of the receipts, so that their capabilities may be fairly and publicly tested. At first we believe that it is intended to employ the steam carriages for branch traffic, but subsequently the system may probably be extended. The company also propose to lease and work railways, and tramways, and let locomotives and rolling stock, and we do not doubt that they will find full scope for their operations.

New Method of Steam Generation.—Some notable results have lately been obtained by means of the circulation of a stream of mercury in a coil of pipe. The lower end of the coil receives the heat, while the upper end distributes it to the water.

---

THE MEASURE OF POWER AND FORCE.

Professor Henry F. Walling of La Fayette College, in referring to an article on this subject published in the "Chemical News."* asserts that the expressions MV and MV^2 are both proper, but independent measures of force; and discusses the subject as follows:—

We may avoid all confusion in this matter by adopting the modern expedient of giving different names to the same agent, in considering the different effects which it causes. If we define force to be that which, when associated with matter, causes it to move, the appropriate measure of quantity of force is "quantity of motion" or *momentum*, represented by *MV;* but when we consider the *work* which is performed, or to be performed, we find it convenient to use a unit of measurement entirely different in its nature from that of quantity of force or motion; and when measured by this unit, we term the acting cause "*power*" or "*energy*." The performance of work may be generally defined as the moving of bodies, or parts of bodies, through certain definite *spaces*, against continuous "resistances," or opposing forces. It may be represented in the form of an equation, thus—$P = ps$, proportional to MV^2, in which P represents the quantity of power or energy; p, the continuous pressure, or its equal, the resistance; and s, the distance passed through.

If any doubt should arise as to which measure is the proper one to make use of, we have only to ask ourselves what kind of effects are to be taken into consideration. In all the operations in which muscular power or motive power of any kind, acting through machinery, is concerned, *space effects* are what we have to do with—that is, we have to estimate the spaces through which matter is moved against opposing force; and ps, or its equivalent, MV^2, becomes the convenient and proper measure. On the other hand, when we consider the effect of a uniformly acting force like terrestrial gravity (within narrow limits), in giving motion to a body freely acted upon, we see that the force which becomes associated will be directly as the time—that is, equal increments of force will be added in equal times; and since we find that equal increments of velocity are also added, we have $F = ft$, proportional to MV: F representing the entire associated force; f, the force developed in a unit of time; and t, the time.

In applying these principles to any "question in mechanics"—that of the railway-train, for instance—it is only necessary to state the question clearly, and its answer is easily given. There are circumstances attending the motion of the train which tend to complicate the solution of the problem, namely, the resistance of the air, friction, etc. Frictional resistance is a consquence of motion imparted to molecules, by which their heat is augmented; the resistance of the air is simply due to its inertia, and thus a large part of the power of the locomotive is consumed in space effects upon the air, and the atoms or molecules of the rails, wheels, axles, etc. Having no exact means of determining the aggregate amount of these motions, we can only ascertain it by actual experiment.

We may, however, simplify the question by supposing the rails to have just sufficient inclination downwards in all parts of the train's progress to exactly balance the external resistances above mentioned. If, now, you would know the *moving force* required to give the train a certain velocity, it is clearly measured by MV, as shown in the previous editorial article; but if you wish to estimate the *work done* in giving it this velocity, or the work the moving train is capable of doing, if rendered independent of the locomotive, as the distance on a level, or up an inclined plane, it will move against a constant resistance, this quantity must be measured in units of its own kind—that is, of ps, proportional to MV^2.

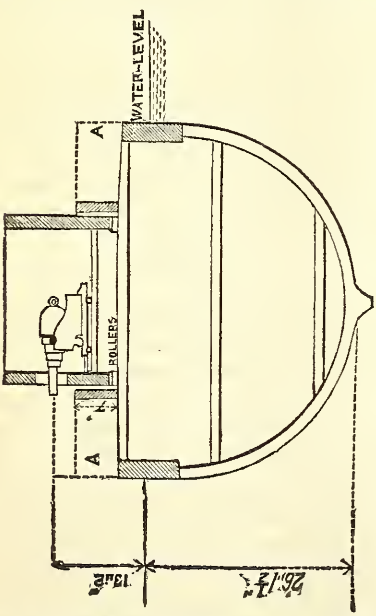
In estimating the amount of coal which must be consumed to perform a certain amount of work, we may suppose that the effect is due to the *falling together* of the atoms of carbon and oxygen, increasing the molecular motion or heat of the compound atoms of carbonic acid thus formed. This motion is transferred to the aqueous molecules, converting them into steam; the molecular motion of the steam imparts motion to the piston of the locomotive, and, finally, to the train itself. The sum of all the atomic weights, or rather attractions, multiplied by the distance through which the atoms have fallen, is the amount of work which they are capable of doing.—Hence the power thus generated is measured in units of ps, and is in direct proportion to the quantity of coal consumed.

We perceive, to sum up, that while MV

*See Van Nostrand's Magazine, No. 3, Page 275.

is the true measure of pure *force*, as an abstract quantity, *ps* or MV^2 is the proper measure for *power* to perform all mechanical operations.

THE NEW ENGLISH TURRET SHIPS.—The House of Commons has recently decided, by a majority of seventy-six votes, that England wants three new men-of-war; and that the best form which these men-of-war could assume was that of turret ships, each 4,400 tons burden, 285 ft. long, drawing 25 ft. 9 in. forward, and 26 ft. 6 in. aft, propelled by twin screw engines, nominally of 800 horse power, and carrying 1,750 tons of coal, assumed to be sufficient for ten days' consumption at twelve and a half knots—the maximum speed to be attained—eighteen days' consumption at ten knots, and twenty-five to thirty days' consumption "at a low rate of speed," a slightly indefinite parliamentary phrase. The ships are to have no masts, and will each carry two turrets, and two twenty-five ton guns mounted in each turret. The freeboard of these vessels is to be $4\frac{1}{2}$ ft. only. The bases of the turrets are to be protected by a heavily armored breastwork, 7 ft. high. The guns will be raised above the water 13 ft. 2 in., and will fire over the breastwork.



The cut, which we take from "The Engineer," is rather a sketch than a working drawing, but shows the general design. These vessels are criticized by some authorities, and approved by others. They will undoubtedly prove useful and efficient, especially in the steam engineering department, and their adoption shows the growing appreciation not only of the turret, but of the Ericsson system.

ON THE CENTRIFUGAL FORCE OF ROTATING SHAFTS.

By W. J. Macquorn Rankine, C.E., LL.D., F.R.S.

From "The Engineer."

1. *Object of this Communication.*—The object of this communication is to explain in a form suitable for practical application, the results of a mathematical investigation of the action of the centrifugal force in long lines of shafting; an action of which no similar investigation has, to my knowledge, been hitherto published; although it is one which may seriously affect the strength, durability, and economical working of machinery.

2. *Centrifugal whirling described generally.*—In Fig. 1, let A and B represent bearings at the two ends of a rotating shaft, and A B its axis of rotation. Any small deflection of the center line of the shaft from the axis A B gives rise on the one hand to centrifugal force, tending to make the deflection become greater, and on the other hand to an elastic stress, resisting the deflection, and tending to straighten the center line again. The resistance to deflection may be shortly called the *stiffness*. For very small deflections, the centrifugal force and the stiffness both increase according to the same law, being both sensibly proportional to the deflection simply; hence whichever of them is the greater for an indefinitely small deflection, continues to be the greater until some deflection is reached which causes a sufficient difference between their laws of variation. The consequence is, that if for an indefinitely small deflection the centrifugal force is equal to or greater than the stiffness, the shaft must go on permanently whirling round in a bent form, as shown by the curves A D B, A *d* B, to the injury of itself and of the adjoining machinery and framing: a kind of motion which may be called *centrifugal whirling*. On the other hand, if for an indefinitely small deflection the stiffness is greater than the centrifugal force, centrifugal whirling is impossible.

Fig. 2 represents by the curves E G, E g, the centrifugal whirling of an overhanging end of a shaft, the direction of whose axis of rotation E F is fixed by the bearing at E.

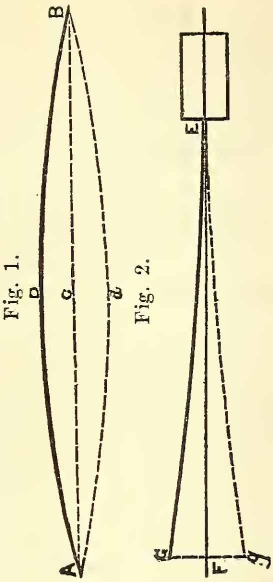


Fig. 1. Fig. 2.

For a shaft of a given length, diameter, and material, there is a limit of speed, and for a shaft of a given diameter and material, turning at a given speed, there is a limit of length, below which centrifugal whirling is impossible.

3. *General Nature of the Investigation.*—The mathematical expression of the conditions of the problem leads to a linear differential equation of the fourth order, integrable by means of circular and exponential functions. The integrals are (as might have been expected) identical in form with those obtained by Poisson in his investigation of the transverse vibrations of elastic rods (*Traité de Mécanique*," vol. ii., § 528); and some of the numerical results calculated by Poisson are applicable to the present problem. The relation between the limits of length and of speed depends on the way in which the shaft is supported. The only two cases which will here be given are those represented in Figs. 1 and 2, viz., the shaft supported on two bearings at its ends, and the overhanging shaft with one end fixed in direction. The general equations, however, enable the problem to be solved for an indefinite number of different ways of supporting the shaft.

4. *Formulæ.*—Let g denote gravity (= 32.2 ft., or 9.81 meters per second); H, the modulus of elasticity of the material, expressed in *units of height of itself* (say about 8,000,000 ft., or 2,400,000 meters for wrought iron); r, the square of the radius of gyration of the cross section of the shaft about its neutral axis $\left(=\frac{\text{diameter}}{4}\right.$ for a cylindrical shaft; $\frac{\text{diameter}}{\sqrt{12}}$ for a square shaft, etc.) and a, the angular velocity of rotation ($= 2\pi \times$ number of turns per second). Calculate a certain length, b, as follows:

$$b=\left(\frac{\mathrm{H}\, g\, r^2}{a^2}\right)^{\frac{1}{4}} \quad . \quad . \quad . \quad (1)$$

Then the limit of length, l, below which centrifugal whirling is impossible, bears a ratio to b, depending on the manner in which the shaft is supported, for example:

Shaft supported at the ends,

$$\left.\begin{aligned} l &= \pi b; \\ &= 3.1416\, b \end{aligned}\right\} \quad (2)$$

Shaft overhanging; direction of one end fixed,

$$\left.\begin{aligned} l &= 0.595\,\pi\, b \\ &= 1.87\, b \end{aligned}\right\} \quad (3)$$

In practical calculations it may be convenient to put instead of $\frac{g}{a^2}$, $\frac{\mathrm{A}}{n^2}$; where n is the number of revolutions per second, and $\mathrm{A}=\frac{g}{4\,\pi^2}$ (= 0.815 ft., or 0.248 meter, nearly) is the altitude of a revolving pendulum which makes one revolution in a second. This gives for the value of b,

$$b=\left(\frac{\mathrm{H\,A}\, r^2}{n^2}\right)^{\frac{1}{4}} \quad . \quad . \quad . \quad (4)$$

It is obvious that r should be expressed in the same units of measure with H and A; for example, in feet, if they are expressed in feet.

The inverse formulæ, for the limit of speed below which centrifugal whirling is impossible in a shaft of a given length, l, are of course as follows: Make $b = 0.3183l$ for a shaft supported at the two ends . . (5) or $b = 0.5347l$ for an overhanging shaft, (6) then the limit of speed, in revolutions per second is

$$n=\frac{r\sqrt{\mathrm{HA}}}{b^2} \quad . \quad . \quad . \quad . \quad (7)$$

The following are approximate values of H A, and its square root and fourth root, for British and French measures:

	HA	$\sqrt{\mathrm{HA}}$	$(\mathrm{HA})^{\frac{1}{4}}$
Feet, . .	6,520,000	25,500	160
Meters, .	595,000	7,700	88

5. *Shaft with additional Load.*—An additional mass turning along with the shaft, such as a pulley, has little effect on the centrifugal force when it is in the usual position—that is, close to or near to a bearing.

The effect of an additional rotating load distributed uniformly along the shaft may be allowed for by diminishing the height, H, of the modulus of elasticity in the same proportion in which the weight of the shaft itself is less than the gross load.

The effect of an additional rotating load at a point not near a bearing has not yet been investigated. The problem is capable of solution by means of the general integrals already known; but it is not of much practical importance ; for when a shaft is so long and so rapid in its rotation as to require precautions against centrifugal whirling, the first precaution is to avoid loading it with rotating masses which are not very near the bearings.

Glasgow University, *April* 2, 1869.

CONSERVATIVE ENGINEERING.

From "The Engineer."

Some twelve months since a pair of very handsome Corliss engines were put to work at Woolwich Arsenal. These engines have 26 in. cylinders or thereabouts, and are got up in a style which leaves nothing to be desired. They may be taken as types of the most advanced practice of the day and as such we speak of them here. From records carefully kept it appears that their average consumption of very good coal is a little over 3 lb. per indicated horse-power per hour. We think most employers of steam machinery will agree with us that this is a most excellent performance, very few stationary engines of moderate dimensions in our manufacturing districts burning less than 3.5 lb. or 4 lb. of coal per horse-power per hour. As far back as 1850 it was calculated that in the cotton factories of Lancashire the average consumption of coal was between 6 lb. and 7 lb. per indicated horse-power per hour, consequently, at first sight, the Woolwich Corliss engine, taken as a type, shows that very great improvements have been made in steam engines during the last twenty years or so. At the risk of astonishing our readers we venture to assert that the improvement exists more in imagination than in reality. In other words, steam engines are now, with certain exceptions, as regards the consumption of fuel, very much what they were in the day of James Watt, who was not quite such a fool as some modern engineers would have us believe. It would not be difficult to adduce hundreds of cases to prove our proposition ; one will perhaps suffice. Not long since we indicated a small factory engine constructed by Boulton and Watt, and started in 1811. Our diagrams showed that this engine was working to about one half more than its nominal power. Its consumption of indifferent slack was little more than $4\frac{1}{2}$ lb. per horse-power per hour. For repairs during the sixty years the engine has been at work, almost without intermission, it has cost little or nothing, and it is at this moment in excellent condition. Here, then, we have evidence, allowing for the difference between coal and slack, going to show that the most improved engines of the present day are really but 1 lb. of coal per horse-power per hour better than those built half a century since. As to durability, when a steam engine of what is now the modern type has lasted half a century and is still in good condition, we shall be happy, if still living, to admit that work done in 1869 was at least as good on the whole as that of our forefathers.

It is the custom with too many feeble-minded engineers to run down and depreciate the works of the mighty heads and hands that have gone before them. The custom is objectionable, and to be deprecated by every right-thinking man. We have quoted the case of the Corliss engine of 1868 *versus* the Watt engine of 1811 to show that, as regards factory engines, at all events, there is no foundation for the assumption that the modern engineer has beaten, and always can beat, his predecessors by an immense distance ; and nothing would be easier than to cite hundreds of other examples, selected from both the civil and mechanical branches of the profession, all demonstrating the great truth that the men who have passed away from among us, not only originated great inventions, but developed them, and gave them to us so far perfected that we find it no easy task to improve upon them. He must be a clever man who can beat James Watt, or George Stephenson, or Isambard Brunel on what they made especially their own ground ; and nothing is, we think, more unjustifiable than the assertion, but too often made, that these men and their work will not bear favorable comparison with the engineers of the present day, and the deeds of the last dozen years. We have no doubt whatever that the assertion is based on honest convictions—if any conviction can be regarded as honest, the reasons for which have not been thoroughly sifted by those who hold to them. But this fact has not sufficed to save many clever men from commercial shipwreck, or to elevate others from the great mass of snobs—Thackeray used the word, so we need not apologise for it—Radicals in mechanical science, the first held that all that had gone before their time must be susceptible of improvement; and disdaining to believe that engineers of sense and skill had ever lived till they were born, they launched out into extravagance, and, enamoured of change they adopted it for its own sake. For a time such men dazzle the world, and then they simply go out, and their place knows them no more. A little more conservatism of spirit, a little perception of the great truth that to change for the sake of changing is a mistake, a little more faith in the mental powers of the engineers who have passed away leaving their works behind them as everlasting testimonies to their skill, would have enabled many a modern engineer to win honor and gold, instead of that disappointment and penury which he has brought on himself by a reckless neglect of the teaching of the past.

Let it not be thought that this article is written without a special purpose, or that it is based on theoretical considerations. We write it with the special object of warning the rising generation of engineers against a fatal error which young men are but too willing to fall into. This error consists simply in holding that little or nothing is to be learned from the works of the last generation. Most young mechanical engineers determine that the moment they get a chance they will originate something great, or produce something in steam or general machinery which shall surprise the world. No greater blunder could be committed. If the young engineer has talents, he will find in the works of the past generation much to admire, something to avoid, and a great deal to imitate. If he lacks talent, his only chance of success is to adhere to the beaten track of precedent. In either case it is well to bear two facts in mind. The first is, that there is no more certain road to success than the power of utilising the experience of others; and the second, that innovating on established practice, is one thing, while making money is quite another.

We do not wish to be misunderstood. While advocating a conservative policy in engineering, we have no wish to stifle invention, or to bar progress by so much as a spider's thread. There is still enormous room for improvement in numberless departments of engineering, and we wish God speed to every one who endeavors to effect it. What we deprecate here is not the true spirit of improvement, but the false light, which, taking its rise in ignorance and vanity, leads men to commit great blunders, and to ensnare an innocent public in the net of destruction, yclept a limited company. Those who honestly determine that they will improve on what has already been done in any special branch of the profession, must begin by learning thoroughly what has been done, what remains to be done, and what those who have done part, have thought, and said, and written upon the subject as a whole. No true progress can be made in engineering science by him who treats the works of a past generation with contempt simply because they are old; and as years and experience come to men they will begin to perceive the truth of arguments which our younger readers may feel just a little disposed to pooh pooh. Facts crop up, indeed, every now and then in a curious and unexpected kind of way, as, for example, that which we cited in the first paragraph of this article, which should suffice to convince the most sceptical that at least sixty years ago engineers might be found in England quite as clever as any who have been born since; and the circumstance conveys a very important lesson, by which certain modern engineers would do well to profit.

CALCINATION OF IRON ORES.

From "Engineering."

Some months ago we drew attention to the ovens designed by Mr. Aitkin for this purpose, and gave a general description of their objects and construction.* Since that time we have received an account of the results obtained by the use of these ovens for roasting corbonaceous iron ores, such as blackband, and those results appear to justify very fully the opinion we formerly expressed as to the value of Mr. Aitkin's method.

The trials were commenced at the Almond Iron-works in Scotland early in 1868. Previously to that time the average make of the furnace had been from 515 tons to 720 tons per month, and the consumption of materials per ton of pig iron made had been on the average:

Coke.	Iron Ore.	Lime.
cwt.	cwt.	cwt.
$27\frac{1}{10}$	38	10

Actually the fuel used consisted of about one-third coke with two-thirds raw coal, and the corresponding proportion of coke has

* See "Engineering," vol. vi., pp. 501 and 552.

been calculated on the basis that 1 ton of coke equals 2 tons of raw coal.

Since the commencement of the trials this furnace has been worked with coked ironstone in the proportion of about 40 per cent., and about 60 per cent. of a mixture of one-sixth of a poor lean blackband, put in calcined, and of five-sixths clay iron ore, very difficult to reduce in the furnace, and sometimes containing as much as 20 per cent. of silica after calcination.

The coked ironstone has been analysed by Dr. Penny, who reports it to have the following composition, viz.:

	Per cent.		
Metallic iron	16.23	= iron	16.23
Protoxide of iron	36.29	= ,,	28.06
Peroxide	trace.		
Sulphide	2.09		1.33
Lime	1.07		
Magnesia	2.50		45.62
Phosphates, &c	3.63		
Silica and clay	8.00		
Fixed carbon	27.20		
Water	2.60		
	99.61		

By the analysis of Staffordshire blackband similarly treated, the amount of iron in the metallic state was 36.48; that of protoxide, 33.66 per cent. The slag obtained in working the furnace with calcined ore was found to be very free from metallic iron.

During the eleven months that calcined ore has been used, the make of the furnace has been on the average, 600 tons per month, ranging from 567 to 741 tons. The consumption of coke per ton of pig iron made has varied from 1 ton 8 cwt., when only 8 per cent. of the coked ironstone was used, to $17\frac{1}{2}$ cwt. when the proportion used amounted to $42\frac{1}{2}$ per cent. Throughout this period the proportion of the coked ironstone was gradually increased from $8\frac{1}{2}$ per cent. to $42\frac{1}{2}$ per cent., and the tabulated quantities of fuel consumed, show that the saving of fuel was proportionate to the amount of calcined ore in the working charge. With the largest proportion of the coked ironstone, this saving amounted to 35 per cent., or $9\frac{1}{2}$ cwt. of coke per ton of pig iron made, for in the place of the former average consumption with raw ironstone of 27 cwt. per ton of pig iron, the consumption with coked ironstone was only $17\frac{1}{2}$ cwt. per ton of pig iron. This fact considered, together with the refractory nature of the clay ironstone amounting to more than one-half the burden, would seem to afford conclusive evidence that a very great advantage is to be gained by calcining the iron ores of a carbonaceous nature according to Mr. Aitkin's method, and that there would be a great probability of effecting a still more considerable saving of fuel in the smelting of the ore if the whole burden of the furnace were coked black-band.

The Shotts Iron Company have lately commenced working with coked ironstone. Formerly the burden of the furnace consisted of $14\frac{1}{2}$ cwt. coal and $14\frac{1}{2}$ cwt. calcined ironstone, and since using the coked ore it has been only $3\frac{3}{4}$ cwt. of coal to $14\frac{1}{2}$ cwt of ironstone.

The amount of fixed carbon in the coked blackband above referred to is equivalent to about $5\frac{1}{2}$ cwt. of coke per ton of the ore, and since that would be to a great extent burnt away by calcining the ore in open heaps, it must be regarded as so much fuel saved. Besides this, the calcination in close ovens admits of the volatilisable portion of the bituminous contents of the ore being turned to account either as fuel or otherwise. This is a further source of saving; besides this, it must be remembered that by calcining in close ovens the oxidising influence of atmospheric air is excluded, and consequently the work of reducing the ore may be in part performed in the calcining kiln, leaving so much the less to be done in the blast furnace, as is shown by the amount of metallic iron in the coked ironstones referred to above.

Any one who has seen blackband ironstone calcined in the open air calcining heaps must have been struck by the enormous amount of combustible material that is being simply got rid of in that operation, and by reference to the analyses of this ore it will be evident that the carbonaceous portion which has hitherto been almost entirely wasted, may amount to as much as three-fourths of the fuel subsequently used in the blast furnace for reducing and melting the ore. Mr. Turran* has estimated the possible saving to be effected by substituting kilns for open air calcination, as amounting in the case of Scotch blackband to as much as 10s. per ton of pig iron, and his experience at the Dowlais Works of calcination in kilns as compared with open air calcination, is decidedly in favor of the former plan, for even after allowing for the interest of outlay for kilns, the cost of labor and fuel is much less with open air heaps.

* The Iron Manufacture of Great Britain, p. 15.

Such a mode of effecting economy of fuel in a business where the gross quantity of fuel consumed is so enormous should receive the earnest attention of those concerned, and there is probably no case in which such economy and reduction of working expenses is more necessary than in iron smelting. We therefore hope Mr. Aitkin's plan of calcination may be taken up by ironmasters actively, and that we may soon be in a position to report its extensive adoption.

REVOLVING SODA FURNACE.

Translated from "Annales du Génie Civil."

M. Lamy, professor of Chemistry at the Central School of Arts and Manufactures, made, at a recent session, a communication on the subject of "revolving furnaces," as used in England for the manufacture of soda. The material so designated is the carbonate of soda, which, according to its various forms, is called "crude soda," "sal soda," or "crystalized soda." It is an article of prime necessity, being indispensable in the manufacture of glass, soda, bleaching material, and in numberless other arts. Its production is an important branch of French industry. An important accessory result is the increase in the manufacture of sulphuric acid, which is largely used in the process.

The production of artificial soda, by the way, is altogether an art of French origin, being invented by Leblanc, whose name and deeds are too little remembered in France. It is remarkable that the process employed, the apparatus, and even the proportions of the mixture, are the same as those used by the inventor, notwithstanding all the research which has been made during three quarters of a century with the design of improving them.

M. Lamy describes the manufacture by the use of sulphate of soda, chalk and charcoal, heated to a pasty fusion in a reverberatory furnace called a soda furnace. The reaction takes place at a high temperature by means of vigorous stirring, which requires the work of skilled laborers, strong and intelligent, and receiving therefore, liberal wages. Crude soda is thus produced, from which, by lixiviation and crystalization, is extracted the 30 to 35 per cent. of carbonate contained.

The French manufactories produce annually about 100,000 tons of the various salts of soda, and in England, where the production is largest, it amounts to 300,000 tons. The high price of the requisite labor has led to a vigorous search for some substitute for manual labor. Two systems have been proposed; the first, that of Mr. Pattinson, effects the mixture by means of iron agitators attached to a spindle, fixed in the center of the furnace, and receiving its motion from a steam engine. This system was speedily abandoned. A more successful attempt is the revolving furnace of Messrs. Elliot & Russell, perfected by Messrs. Stevenson & Williams, at the chemical works at South Shields near Newcastle. It consists of a large cast iron cylinder about 5 meters long (horizontally) and 3 meters diameter, lined in the interior with refractory bricks. Its interior space is not cylindrical, but is enlarged in the middle, in order to keep the materials in the center—shaped in fact like a cask. It has also, in the interior, two longitudinal ribs, situated diametrically opposite each other, in order to effect more thoroughly the mixture during the revolution. The cylinder rests upon four friction wheels, which are supported upon a massive frame. On the exterior circumference are teeth, gearing with a pinion driven by the engine at any desirable speed. The charging hole is in the middle of the circumference, and closed by a cast iron gate. The openings at the ends serve, one for the introduction of fire from an adjoining furnace, the other, for the escape of the products of combustion, which are carried off into various accessories, and utilized in the solutions, evaporation and lixiviation. The communication of fire to the cylinder is made by means of a movable flue, held by a chain, and lined with fire brick, without which, small and unforeseen derangements might cause accidents. A great amount of fire is indispensable to a sufficiently energetic action throughout the whole of the furnace. To "cook" a charge of soda, the cylinder is raised to a red heat, and turned into such a position that the charging hole corresponds to a chute, in towhich the barrows dump the materials for the charge, which consists of 1,300 kilog, of carbonate of lime, 500 kilog of coal, broken up quite small. The cylinder is then given ten revolutions per hour, or a turn in six minutes. After an hour and a quarter the lime is calcined, and there is then added to the charge 1,160 kilog of sulphate of soda, with 180 kilog of coal, and the cylinder is revolved at the same rate half an hour longer. At the end of that time the reaction commences with the fusion of the materials, and the velocity is increased to two turns per minute. The operation terminates in about half an hour at this rate of rotation. The cylinder is stopped with the charging hole at the lowest point, and the semi-fluid soda is drawn off into vessels moving upon tram-ways underneath.

This operation lasts two hours and a quarter, and admits of six heats and a total production of 18,000 kilog of crude soda in 24 hours, which is three times the product of an ordinary good English furnace. The heat is distributed in the most uniform manner, the sulphate is more perfectly decomposed, the operation more completely protected from the access of air, the manual labor greatly diminished, and the consumption of coal reduced in the ratio of 362 kilog to 544 or about one third. It was found at the outset that the plant was very expensive and subject to frequent disarrangement. Lately, however, the patents have expired, and the details of the furnace have been perfected so that it works with all desirable regularity, and costs, in England, not more than 35,000 francs. Mr. Stevenson has mounted four of these furnaces in his establishments, and a dozen others are working elsewhere in England—notably at Widness and St. Helens. They are built by Mr. Robert Daglish at the St. Helens foundry in Lancashire.

PULLEYS WITH LEATHER COVERING.

Translated from "Polyt Centralblatt."

The sliding or slipping of belts on the pulleys is an evil experienced by almost every one whose business depends on machine power. Various means have been devised to avoid it. One of them is to strew powdered rosin or pitch on the inside of the belt. Another is to cover the pulleys with wood. A third is to give the rim of the pulley a curved surface. These means are only palliatives, and lack a thorough, steady and continued action. Rosin and pitch are soon pressed into the leather, when they not only lose their efficacy, but contribute to the rotting and destruction of the belts. A wood covering on the pulley gets polished in a short time and is then as slippery as iron. It is therefore necessary to frequently roughen its surface, by which operation the diameter of the pulley is diminished and the proportions of the transmission are altered. A convexity of the rim of the pulley is very effective to prevent the dropping off of the belt, especially when the pulley has a horizontal position; but it counteracts the slipping of the belt to but a small extent.

We therefor take pleasure in communicating to the public a mechanical contrivance, which completely prevents the sliding of belts and all the great disadvantages resulting from it. It consists in covering with leather the working-surface of the pulleys. As the friction of leather on leather is equal to five times that of leather on iron, and as leather can be roughened and be easily kept in that condition, it is evident that a sliding of the belts cannot take place on pulleys covered with leather, not even then when the belts have to transmit the very highest amount of power. We have seen such pulleys working in sugar factories, breweries, in manufactories of German silver, in paper mills, machine shops, sawing mills and in many other mechanical establishments, in all of which they have proved of eminent usefulness and great practical value. With pulleys which have to run with a great velocity, as, for instance those that have to drive blowers and saw-frames, as well as with pulleys of small diameter, which have to transmit powerful strains, the advantages of a leather covering are especially great. But besides these evident advantages that result from the avoidance of the slipping, a leather-covering on the pulley preserves the belt; in the first place because the belt does not require tightening so hard, the friction being considerably increased; and in the second place because there is no occasion for a rapid rotting of the belt. For this rapid rotting is generally caused by the fact, that under the influence of the heat produced by friction the tannic and sebacic acids contained in the leather of the belts, combine chemically with some of the iron of the pulleys, forming a hard compound in the belts, which produces what is called rottenness and frequently causes breakages. This evil is of course avoided by covering the pulleys with leather. These covered pulleys are manufactured by Mr. S. Freund, Jr., 8 Neuenburger Strasse, Berlin, (Prussia). The coverings are fixed to the pulleys by a kind of paste or glue, which hardens in a very short time and sticks so well to iron and leather, that the greatest forces can be transmitted by the pulleys without loosening the leather. The operation of covering is very simple and can be done and renewed by every intelligent workman. The mentioned factory is prepared to send coverings and glue abroad, together with full and explicit directions showing the way to put them on. The price is $1\frac{5}{6}$ Prussian thalers per square foot of leather, including the glue. (Berggeist.) S.

MERCHANT MARINE.

ADVANTAGES OF IRON SAILING VESSELS.

Translated from the "Revue Maritime et Coloniale."

It seems tolerably certain that iron sailing vessels are to play an important part in the future of the merchant marine. They are more substantial, more durable, and of greater carrying capacity, than wooden vessels of the same displacement. They attain also as great speed, or even greater, for they may be constructed of greater length, and their capacity increased, while maintaining the same spread of canvass, and consequently the same equipage. The length may be six times the beam, in an iron vessel, without interfering with facility of manœuvering. The damages to a metallic hull may be repaired, at least provisionally, in almost any part without interfering with its serviceability, or capacity of continuing its voyage. At sea, iron ships behave as well as wooden ones, and resist better the stress of storms.

For East India navigation, iron hulls are free from all fears of rot, which at the end of six or seven years, and sometimes earlier, attacks wooden vessels engaged in carrying fermentable cargoes, such as rice, sesame, etc. Moreover, French vessels which frequent Indian seas, being generally of small or moderate tonnage, often find it advantageous to obtain local employment there, when a return to Europe holds out no hope of profit. But it often happens that wooden vessels cannot avail themselves of these opportunties, either through fear of having to go into dock in a foreign country, or to make repairs at some far-off port, which are enormously expensive. With iron vessels these inconveniences are avoided.

At Calcutta there are always about forty or fifty iron vessels, of about 50,000 tons altogether, which always obtain preference to wooden vessels, and generally at a higher price. It is well understood by shippers at that port, that iron vessels generally deliver their cargoes in a more satisfactory condition than wooden ones. Masts and lower yards of iron and iron top-sail yards have also great advantages, both in respect of durability and staunchness. Some English vessels have also the top-masts and standing jib-booms of iron. Iron wire rigging is generally adopted in vessels making long voyages. A suitable application of paint to protect the bottom is indispensable for the preservation of plates and rivets. Great care is necessary in taking such a vessel into dock, since it will not take paint properly until it has been scraped, scoured, washed, and perfectly dried. After a passage of one hundred days from Cardiff to Calcutta, the writer's vessel had not diminished her speed at the end of the voyage.

It is desirable that the French *Veritas* adopt for iron vessels the system of classification of the English Lloyds.

Sanitary Treatment of the Refuse of Towns and the Utilization of Sewage.—Mr. Menzies lately read a paper on this subject before the Institute of Surveyors. The paper, besides dealing generally with the subject, was devoted to an exposition of the "separate system" of drainage of which Mr. Menzies is the originator. That system is, that the rainfall shall in all cases, as a principle, be entirely separated from the sewage; the rainfall being conveyed to the nearest outlet, and the sewage to the most appropriate land for utilization. The advantages claimed for the idea are many. The first anticipated is, that there will be no gullies or openings into the streets communicating with the foul drains by which effluvium can rise into the streets or courtyards; the second, that men will not require to enter into the drains to clean out the sand and grit from the roads; the third, that no over-flows of foul or sewage matter will be necessary; and the fourth and most important, that the treatment at the outlet by irrigation will be uniform, economical, and practically perfect. The fifth advantage is, that perfect and continuous removal of all sewage may be secured by a complete system of flushing, under command at all times and at all seasons; and it is worth observing that the greatest flushing will be necessary, or rather desirable, in the town in dry weather, just when the fields outside will take it best. The sixth advantage is, that when pumping is necessary, as it is in such a vast number of cases, the economy will be very great. The idea was first brought before the public by Mr. Menzies in 1865.

THE BESSEMER FLAME.

From a paper read before the Philosphical Society of Glasgow, by Thomas Rowan, F.C.S., F.R.S.S.A., Atlas Works, Glasgow.

The Bessemer process for the manufacture of steel is now among the most important of our metallurgical operations, the chemical changes being as interesting as the mechanical appliances designed for the working of the process are ingenious. On account of its comparatively recent introduction among established industries, it affords an ample field for scientific investigation; and there is no feature of the process at once so interesting and important as that of the flame which issues from the "converting vessel."

The success of a "blow" undoubtedly depends on the accuracy and completeness of many details, but, of them all, the most important is to know and catch that moment in the existence of the flame, when the carbon in the iron has yielded its last trace to the oxygen of the air.

If a charge is "overblown," that is if it be subjected to the action of the air for too long a period, or if it be "under-blown," that is if the admission of air is stopped before the proper chemical action has been completed, the steel will be found to be defective in proportion to its unskilful treatment.

The flame issuing from the converter is the index of these changes which the molten mass of metal is undergoing during the process; but the exact moment of decarburisation is often, from a variety of causes, difficult to determine.

It is for these reasans that the examination of the flame forms the point of attraction of the process, and I have thought it might not be uninteresting to describe the general appearance which this flame presents to the eye, and some experiments which my brother has made with the spectroscope, and with colored glasses, for the purpose of more readily determining that critical period or "change" in the flame which I have spoken of. The success of these latter experiments has enabled him to attain the object for which they were commenced, and he has designed an instrument, which I shall describe hereafter, by which the "change" in the flame is more easily determined.

1. THE GENERAL APPEARANCE OF THE FLAME TO THE EYE.

When the vessel is first turned up a shower of brilliant sparks is ejected owing to the force of the blast reaching first a thin layer of metal as the vessel slowly swings round to the vertical position.

From 0° to 3 or 4 minutes.

When the full head of metal is over the blast, at first for three or four minutes, there is scarcely any flame, only a current of very hot gases and very numerous sparks.

From 3 or 4 to 5 or 6 minutes.

Gradually a small pointed flame appears in the centre of the sparks, and this quickly increases in size without gaining much brilliancy for two or three minutes.

From 5 or 6 to 9 or 10 minutes.

During the next period of 4 or 5 minutes the flame is very unsteady, both in size and in position, and its oscillations are accompanied by hollow sounds as of reports or explosions in the interior of the converter.

From 9 or 10 to 11 or 12 minutes.

Streaks or flashes of brighter flame now shoot up through this comparatively non-luminous flame, and within 1 or 2 minutes give place to a continuous stream of dense and brilliant fire which rushes far up the chimney and illuminates the entire building, often casting the shadows of the cranes, etc., against the windows through which the sun is shining.

From 11 or 12 to 15 or 16 minutes.

This flame gradually becomes thinner and more transparent without losing any of its brilliancy during the 6 or 7 minutes of the "blow," which generally remains, until it suddenly (preceded, however, by a few hollow and peculiar sounds from the interior of the vessel), loses its brilliancy and much of its size, and drops down within about half a minute to about the size it had reached at about 5 minutes of the blow, this flame, however, being both more dense and more luminous than the flame at that earlier period.

Any of the stages described may, from a variety of causes, be prolonged; or an insufficiency of blast, howsoever caused, may lengthen the entire period of the "blow" for several minutes, but the above is a fair average "blow" with the best English hematite pig iron. If inferior irons are used the flame at the change is more or less enveloped in a dense white smoke, and the change is accompanied by violent pulsations or "coughing" of the entire flame, which, under these circumstances, has often a yellowish red color to the eye, all this making the change often very difficult, if not impossible, to detect.

Nervousness or biliousness, by variously affecting the sight of the observer, may also render him unable, *with certainty*, to determine the precise moment when he ought to "turn down," and there is a marked difference in the facility of observation noticeable between a blow taking place in daylight and one at night.

2. THE APPEARANCE OF THE FLAME.

It was important, first, to note if any of the lines belonging to the Bessemer flame were to be found in the flame given off from the coke fire used to heat up the "converter." Several examinations were made; the result of these was that, besides the invariable yellow bright line, the red line and the two bright green lines next the yellow were occasionally to be seen. Owing, however, to the want of brilliancy of this flame, the spectrum which it gave was very faint, and at times almost invisible.

On first turning up the vessel, and for about four minutes thereafter, the spectroscope showed only a continuous band of light, with the colors rather hazy, and so much blended with one another as to make it impossible to mark the junction of the different fields.

In from four to six minutes flashes of the yellow line became visible (corresponding to the appearance of tongues of a bright flame shooting up in the centre of the dull red one issuing from the mouth of the "converter"), and in one or two minutes after its first appearance, this line became quite steady, and did not disappear even at the end of the "blow." Simultaneous with the steadying of the yellow line, the red, yellow, and green fields became clear and well-defined bands of bright color.

In half to a minute later a bright green line appeared near the yellow, following which, in scarcely ever more than half a minute, a red line appeared equidistant from the yellow (of course on the opposite side). These two generally became steady together (having first appeared in intermittent flashes) in about half a minute after both were visible. With the steadying of these two lines, at once a second green line (bright and about the centre of the green field) became visible, wavering a little at first. About a quarter of a minute served generally to steady it, although sometimes it was a minute and a half from the appearance of the first green line till the second green line with the red became steady. In one to two minutes a third green line nearer the blue field came into view, and in about one minute was steady.

When the red appeared with the first green line, the second and third green lines generally appeared together, but when the red appeared with the second green line, the third green was accompanied by a blue bright line near the green field. In about ten minutes after turning up the converter the flame attained its maximum size and intensity of light; when a second and third bright line became visible in the blue field; very often these were only intermittent and very faint, but with "hot metal" and a bright flame they were pretty steady and distinct and were broader than those in the yellow, green, and red fields.

Occasionally, for about two or three minutes before the close of the blow, a bright line was seen in the purple field, pretty far to the right of the spectrum. Sometimes this only flashed brightly, but on a few occasions it was clearly seen, though faint.

With a very bright flame several dark lines were seen, but for want of definiteness it was impossible to say whether they were not due to the contrast afforded by the brilliancy of the bright ones besides which they appear. A narrow, dark line was seen on each side of the red line, and a broad, dark band dividing the yellow from the green; then one between each green line, and two in the blue field between the three blue lines. But these were only seen with an exceptionally bright flame, and therefore are not of much importance.

All the bright lines visible remained steady for several minutes before the close of the blow, affording an excellent opportunity for their examination; but at the last all, with the exception of the yellow, faded in less than thirty seconds. The purple line disappeared first, whenever it happened to be visible, then the three blue lines in the inverted order of their appearance, then the third green, after which the second, then the red, and last of all the first green, when the blast was shut off.

The green and the red lines, from their distinctness, afforded the best point for a determination of the process; and these were so constant that a sure indication could always be given by any of them, if it were made the index by which to determine the period of blowing.

Very often, on adding the charge of spiegeleisen, a large and very brillant flame rushed out of the "converter" for some minutes; and on examining it the red, yellow, three green, and a very brillant purple line were seen, but no blue line.

3. SOME EXPERIMENTS WITH COLORED GLASSES ON THE FLAME.

I shall now proceed to describe some experiments made with colored glasses on the Bessemer flame. I may mention that what led to them was my brother being compelled to get very dark spectacles to protect his eyes, which were not very strong, from the intensity of the light of the flame. The first pair made completely overcame the brilliancy of the flame without imparting any color to it; but on ordering a second pair they showed so much color as to render them useless. On appealing to the workman who had made them, he found that no note had been kept of the kinds of glasses which had been used in the first pair; and although several attempts were made to repeat them, the second pair sent was the best he could accomplish, and they had appeared colorless to sun light. The thought then occurred that as the brilliancy of the flame varies considerably during its existence, a variation in the *amount* of transmitted light might be found to affect in a proportionate degree the power of some colored glasses to absorb colors in combination with them, and that a combination of colors might be found to give, with a small quantity of transmitted light, a distinct color which could be quite absorbed when a large quantity of light was passed through the same glasses.

Another, and perhaps the most important, consideration which led to the following experiments was, that the flame itself has a varying chemical composition as the silicon, manganese, carbon, and iron becomes successively attacked, and that the *temperature* of the flame at these various stages must necessarily be altered, giving rise of course to various colors or shades of color in the flame. If therefore a combination of colored glasses could be found which would absorb the color due to the flame at a particular temperature, it seemed clear that a *change* of temperature would become immediately visible on account of an accession or diminution of color to the flame as thus observed.

It is probable, too, that some of the color possessed by the flame at its different stages is due to the various elements which are at these periods being volatilised, but the spectroscope does not throw much light on this supposition.

The first combination of colored glasses which I have noted are a ruby and emerald. It was found that these colors mentally destroyed each other.

The Bessemer flame when viewed through them appeared white, and without brilliancy.

Ultramarine blue, dark yellow. This combination gave the same effect as above.

With a combination consisting of ultramarine blue, dark yellow, ultramarine blue, and emerald, the flame appeared of an emerald color, but was dark and without brilliancy.

In the next experiments the dark yellow and one blue were replaced by a light yellow and neutral tint thus; Ultramarine blue, light yellow, nentral tint, emerald. The appearance of the flame in this case was similar in color to that afforded by the above combination, but appeared of considerable brightness.

In the next experiments the light yellow and neutral tint were replaced by a dark yellow and red respectively, thus: Ultramarine blue, dark yellow, ruby, emerald. The flame at first was dimly seen, and without color. When it reached its maximum brilliancy it still appeared white through this combination.

With these five combinations the appearance of the sun as seen through each of them was similar in character to that of the flame, but more powerful in degree.

In the subsequent experiments the combination was as follows: Ultramarine blue, dark yellow, neutral tint, ultramarine blue. The flame appeared at first of a ruby red color, increasing in size and intensity as the "blow" progressed, the edges of the flame acquiring a lighter shade of red; but the color was too strong to admit of the changes being easily determined. Sunlight, through this combination, was slightly yellow.

In the succeeding experiments one of the blue glasses was replaced by a light yellow, giving a combination of ultramarine blue, dark yellow, neutral tint, and light yellow. The flame appeared at first of a yellowish red color. As the "blow" progressed this color became whiter with flashes of redder flame occasionally through it. At the flame's maximum brilliancy the edges assumed a light red color (nearly white), while at the root and center of the flame the color was of a darker yellowish red. When the flame dropped (at the end of the "blow") it returned to a yellowish red color, somewhat similar in appearance to the effect produced at the beginning of the blow.

Sunlight appeared slightly yellow. It will be observed that this combination gave nearly the desired effect, viz, a variation of depth of color due to the differences of temperature or brilliancy of the flame at its different stages of progression.

The yellowish tint, however, always present, showed a defect in this combination, to overcome which, further trials were made. Among other devices the light yellow was omitted, and the flame was observed with ultramarine blue, dark yellow, neutral tint. The flame appeared still red, and with the yellowish tint, though in such small degree as to show that the desired result was not far off.

Sunlight appeared dim and slightly yellow.

In the concluding experiments the neutral tint was replaced by a blue glass, with the object of ascertaining whether the yellow color could be arrested by the omission of the red or the blue component of the neutral tint, thus: Ultramarine blue, dark yellow, ultramarine blue. The combination was perfectly successful, the lingering trace of yellow being removed.

I shall now describe more fully the general appearance of the flame through it.

For the first four or five minutes all is dark, the chimney is invisible; nothing but the mouth of the converter can be made out, which appears slightly red, the sparks coming from it being scarcely visible. As the blow progress the red color increases in size and luminosity, while the outline of the vessel becomes visible.

In about twelve to fifteen minutes the flame begins to lose its color, becoming violently agitated, flashes of a lighter and brighter flame shooting up occasionally.

In about fifteen minutes a purple tint becomes visible round the mouth of the vessel, the flame gradually acquiring a white color towards the edges.

When the flame has reached its maximum brilliancy, it appears bright and nearly white, with the edges purple. The red color thereafter begins to re-appear at the mouth of the vessel and centre of white flame, gradually extending until the whole flame appears of a light red color, and with the peculiar hollow sound heard in the vessel always preceding the drop.

The centre of the flame begins to acquire a deeper color; this quickly extends and deepens. Within a minute or so of the drop, the whole flame becomes crimson, and losing its brilliancy, and within half a minute it suddenly goes back to very nearly the red color it had at starting.

This combination of glasses is now in daily use in the Atlas Works, its indications being so marked and unmistakable as to render its use safe in the most inexperienced hands. This little instrument, or "chromopyrometer" as it is purposed to call it, is arranged as follows:

One of the blue glasses and the dark yellow one are fixed in a rectangular frame, carrying at its foot a hinge, to which the thin frame holding the other blue glass is attached, and at its top a spring catch to hold this smaller frame when in its shut position; and also a pin and set screw for attaching the whole instrument to the hat of the observer, so as to place it before his eyes.

The object of having the glasses thus divided is to give facility for the observation of the flame through the combination of three, while, during the pouring, two being sufficient, the third one is allowed to hang down, when it serves to protect the lips from the great heat of the ladle and liquid steel.

In conclusion, I think it is probable that by carefully noting by means of colored glasses, such as that described, the amount of light (as determined by the shade of color visible) emitted by flames of known temperature, a scale might be formed which would enable us approximately to measure the temperature, not only of the flame of the Bessemer converter, but also that of many flames which have hitherto been considered beyond the reach of our ordinary methods of measurement.

THE MANUFACTURE OF SULPHURIC ACID.

HISTORICAL NOTICE.

Translated from "Le Génie Industriel."

Thirty years ago the only available source of sulphur, for the manufacture of Sulphuric Acid, was the volcanic region, or sol fataras of Sicily. Our national industry was, therefore, in a measure, dependent upon the complaisance of foreign powers, and at the mercy of political and commercial vicissitudes. It was probably this state of affairs that prepared the way for the development of some source of this precious mineral in France. The same stimulus was felt in other countries, and gave rise, no doubt, to the strenuous efforts made to discover within their own soil the means of release from this burdensome dependence. At length, after much research and experiment, the industral world became indebted to a Frenchman, Michel Perret, for the first success in the new path;—a name, unfortunately, too seldom remembered. The first success in obtaining sulphur from pyrites, in the form of sulphurous acid, was attained at Lyons, near which city large deposits are found. This innovation gave to the manufacture of sulphuric acid, and through it to the chemical arts generally, such an impulse that the consumption has increased tenfold within the last thirty years.

Prior to 1833 there was a prevailing impression, derived from numerous unsuccessful experiments, that the sulphurous gases derived from the burning of pyrites, were unsuitable to the production of sulphuric acid. It was generally believed that pyrites would not burn without fuel, and it was therefore roasted with a mixture of coal. The distinguished chemist, Climent Dèsormes, had proceeded in this assumption, in using cupola furnaces, in which he was able to utilize only a small part of the gases so obtained. At that time M. Michel Perret proved that sulphurous acid gas, disengaged by the combustion of pyrites, was essentially well adapted for conversion into sulphuric acid. With this view he constructed in his father's workshop some muffle furnaces, in which he burned the pyrites, without mixing the products of combustion with those of coal, the proportion of air necessary to carry on the condensation in the chambers being very carefully regulated. This surmounted the difficulty satisfactorily. The date of the first patent for fifteen years was February 2d, 1836, and it was taken out in the name of his father, who had encouraged him in his labor and studies. The young man, at that time but twenty years of age, showed himself on more than one occasion to be a profound thinker and fertile in new ideas. The success obtained by the application of this process, for several years, on a scale of some magnitude, led to further investigation into means of economizing the combustion. The use of the old furnaces was revived, but without the use of coal. M. Baptiste Perret and M. Olivier, brother and brother-in-law of the inventor, united with him in the work of improving the process, which by their united efforts has reached the stage in which it may now be seen in the factory of St. Fons, near Lyons—one of the principal establishments of the Perret firm. We may mention one of the improvements due to M. Michel Perret, viz: the apparatus for utilizing those portions of the pyrites which are reduced in the crushing process to a state of fine division, constituting a considerable portion of the whole, and which would otherwise be wasted. A small model of the furnace used, arranged so as to show a section through its axis, and giving a complete idea of its construction, is exhibited in the window of the Perret firm, and the use of the process is freely open to all who are engaged in this branch of industry. At a little distance from a layer of pyrites in lumps, burning in an ordinary box furnace, is placed a sole of large refractory bricks, six centimeters in thickness, such as are used for spreading out plate glass. Imagine now seven other similar soles, separated by intervals of six centimeters, in a mass of masonry in which the openings are so disposed that the current of air, coming from the roasted lumps, will envelop in a very circuitous manner the surface of the pyrites in the form of powder or small pellets, spread out upon each sole. Each layer of pyrites, heated by the combustion of the preceding one, burns, either by the direct admission of air into the mass, or by a kind of cementation, requiring thirty-six hours for its completion, to such a stage, that not more than four or five per cent of sulphur remains uncombined. As might be expected, the temperature increases as we approach the upper end of the series. Mr. Michel Perret thought that the number of soles might be increased beyond eight, and he therefore constructed a furnace in which the number was carried to sixteen. But as their superposition gave a great altitude to the furnace, he divided it into two series, parallel with each other, in such a manner that the gas from the eighth and upper sole was carried by a recurved flue over the surface of the lower layer in the second series. In this furnace the temperature steadily increases from the sole where the lumps are ignited to the uppermost layer, showing with what facility the air penetrates the mixture of powder and grains of pyrites, which is spread out to a depth of three centimeters in each layer. It would seem, in order that the air may circulate in the intended manner, that all possible means of access, excepting those provided, should be rigidly closed. This can be readily managed, so far as the back part of the furnace is concerned, the brick forming the sole being built into the masonry. This arrangement will not suffice, though, for the front, since the charging and discharging of the mineral is made on that side through doors opening upon each sole. To obviate this difficulty an interval is left between the front of the sole and the wall, which interval at the time of charging the lower sole is filled with slack, held in place by a closed register. In charging the second sole the slack is let down and forms a "talus" upon the level below. The different levels are charged in this way, successively, from bottom to top. The furnace is charged once in thirty-six hours, and consumes 1,000 kilog. of fine pyrites. As the charging cannot be done in an instant it permits the passage of an excess of air, while it is going on, and possibly this may explain the fact, denied by some, but maintained by many, that this system of furnace requires an excess of nitrate for the amount of sulphur burned.

Altogether these improvements, and the possession of extensive deposits of cupriferous pyrites at Chessy and Saint-Bel, have given a great development to the manufacture of MM. Perret. Their establishment at Chessy, Lyons, Vienna, Avignon and Marennes, furnish nearly 100,000 kilogrammes of acid a day, beside the other products derived from them, such as soda, iron, copper, alum, ammonical salts, hydrochloric and nitric acids, soda, &c., &c. Such an impetus has been given to general industry, in consequence of the discoveries of the firm of Perret Brothers & Olivier, that even their enormous present production of acid is insufficient, and fully twice the amount of pyrites consumed by them has been delivered to French and other consumers for manufacture by this process. In renouncing the monopoly assured to them by the possession of their extensive ore beds, this firm have entered upon a path of liberality which cannot fail to advance greatly the industrial interests of the whole nation, and have set an example most worthy of imitation.

Steam Plowing in France.—At the special trial of agricultural implements at Moulins, in April, the double engine tackle of Messrs. Aveling and Porter took the first prize, and the second prize was awarded to M. Achille Farjas. The next trial takes place this month at Beauvais. The French are imitating the English in these comprehensive and frequent tests.

NOBEL'S BLASTING MATERIAL.

NEW EXPERIMENTS WITH "DYNAMITE."

Reported by Max v. Wolfskron.

Translated from "Oestr. Zeitschrift."

Mr. Nobel's nitro-glycerine, which produces such powerful and astounding effects, has on the other hand caused so many fatal accidents, that a certain awe of its dangerous qualities has prevented it from coming into general use. It is true, there are countries, as for instance Bavaria, where for several years past nitro-glycerine has been used for blasting, without the occurrence of any mishaps; and indeed such accidents can scarcely happen unless by neglect of the necessary precautions. But it is well known that workmen when once familiar with a work that implies some danger, become very careless, and that this carelessness often causes the most fearful accidents. Besides the nitro-glycerine, like all similar compounds of nitrogen, is in itself liable to be decomposed, when the acids produced by this decomposition affect and loosen the soldering of the metallic bottles which contain the fluid nitro-glycerine, thus causing leakage and danger. It is also not impossible that under certain circumstances a spontaneous decomposition of the fluid may take place so rapidly as to produce an explosion. Therefore, whenever it is observed that nitro-glycerine is beginning to decompose, which is easily seen by the red vapors it then emits, the whole portion should be destroyed without delay.

It is not astonishing that the importation and the transport of so dangerous a material should have been prohibited in several countries, and also in Austria. But there was no well-founded reason to include in this prohibition, as it has been done, another matter, called dynamite, which does not possess the above-mentioned dangerous qualities. Dynamite consists of calcined mineral meal from the neighborhood of Lüneburg (Prussia), impregnated with 75 per cent of nitro-glycerine, and mixed with another ingredient, which prevents it from spontaneous ignition. It hardens at 45° F., at which temperature the nitro-glycerine contained in it, congeals. In this condition it cannot be exploded by ordinary means. Charges congealed in the bore-holes must be exploded by caps and cartridges having a higher temperature than 45° F. These cartridges, which also contain the caps, are small, and the workmen can easily carry them in their pockets.

Dynamite has been manufactured at Hamburg by Mr. Nobel, since 1866, and more recently also at Stockholm, in Sweden. In the latter country the dynamite is in general use in the mines and quarries. In Prussian Silesia 8,000 lb. of it are used every month. It is besides largely in use in the mines of Saarbruck, Westphalia, Nassau and Thuringia. Considerable quantities of it have been imported to England and Belgium, in 1868.

A factory of dynamite was established in San Francisco in March, 1868, which factory had already sold 100 lb. of it per day, up to July of the same year. It is used not only in the mines of California, but also in those of Mexico, and in the blasting operations of the Pacific railroad. In California also, as in several European countries, accidents were feared from this new blasting material, and no company would at first undertake its transportation. But afterwards, when various experiments, made before an assembly of representatives of all the transport companies, had proved that these fears were groundless, the dynamite was accepted on all the railroads, steamers and stage-coaches.

The following experiments, for the same purpose, were made on the 22d of March at Hütteldorf (Austria) in presence of a delegation of the Vienna Society of Engineers: A small barrel, filled with cartridges of dynamite, was thrown down from a rock over 100 ft. high and did not explode, though striking the rock repeatedly. Two cartridges were fastened to the lower surface of a heavy block of stone, and the stone was dropped from a hight of over 20 ft. on a stone bottom. The cartridges were smashed and flattened down without exploding, and the dynamite was found in a totally unaltered condition.

Several cartridges were taken out of the above-mentioned barrel; each cartridge was cut in two parts, the one of which was made to explode by the means of a quick-match and a cap; the other part was ignited, and burned off quietly, leaving a small heap of mineral meal.

The contents of a cartridge was spread over a piece of sheet-iron and heated; the nitro-glycerine evaporated without explosion.

A box of sheet-iron, filled with dynamite, was thrown into the fire without producing an explosion. The above-mentioned barrel, filled with cartridges was thrown into the fire, and burned down quietly.

To show that the dynamite cannot be made to explode, except by a strong cap, it was tried to ignite a box of sheet-iron, filled with dynamite, by a quick-match without a cap; but the dynamite would not take fire.

These experiments having proved sufficiently that the dynamite is entirely void of danger, another series of experiments was made to show the powerful effects of this new blasting-material:

A cartridge was laid on a plank of maple-wood, two inches thick, and was made to explode. It struck the plank with great vehemence, making a large hole through it.

As the strange prejudice exists that the dynamite acts better downward than upward, the same experiment was repeated, the cartridge being this time attached to the lower surface of the plank. The effect was the same.

A timber, four inches by five inches thick, rammed into the ground, was torn apart by the discharge of a half-pound cartridge.

Half a pound of dynamite was made to explode on an iron plate a quarter of an inch thick. The plate became perforated and torn; a round piece was torn out of it and thrown to a considerable distance.

But the immense power of the dynamite was proved most strikingly by the following experiment;

A $\frac{7}{8}$ inch hole was bored through the whole length (13″) of a wrought-iron cylinder of 8 inches diameter. This bore-hole was filled with one-quarter of a pound of dynamite and discharged by a Markus battery. The effect was astonishing to a high degree. The cylinder was torn in two pieces. Each piece had two cracks through its entire length, and many smaller ones. The bore was enlarged throughout, in one place to $1\frac{3}{4}$ inch. diameter. The molecular structure of the pieces was totally altered.

The succeeding experiment consisted in bursting a piece of rock without any bore-hole.

Finally, four bore-holes, $1\frac{1}{2}$ inches in diameter, and 3 ft., $2\frac{1}{2}$ ft., 2 ft., and 16 inches in depth, made into the solid rock, were discharged without tamping. The first hole was loaded with 2 pounds, the second with 10 ounces, the third with 8 ounces; the fourth, which was made in the vault of the rock, with only one ounce. The first and third were discharged simultaneously by the Markus battery; after that the second hole alone by the same battery, which also on this occasion proved its excellence. The fourth bore-hole was discharged by a gutta-percha quick-match. The effect of these discharges was satisfactory, though the rock was soft and loose and consequently unfavorable for such experiments. S.

CONDENSATION IN STEAM ENGINES.

By M. E. Cousté, Government Director of Manuf.

Translated from "Annales du Génie Civil."

An important question has long troubled the wisdom of engineers in every country where steam navigation has received any development, viz, the use of steam at high pressures in marine engines. The greatest obstacle to its employment is the excessive incrustation of the boilers from the use of sea water. The English have essayed to solve the problem by the use of surface condensers, which make it practicable to supply the boilers with water, from which the incrustating matters have been eliminated. This contrivance rendered necessary an enormous area of condensing surface, resulting in practical difficulties similar to those which defeated the attempts of Watt, Hall, Cavè, Bourdon, Ericsson, and a host of other engineers. Latterly means have been found of giving to the surface condenser a superficies of more than a square meter per horse power, which has given some good results. I am convinced, however, and I shall attempt in this paper to prove that this solution, though constituting a sort of progress, is founded on a retrograde principle ; that it realizes but a portion of the advantages which may be obtained, and that those advantages cannot be obtained completely, and with certainty, except by the use of the injecting condenser.

I propose then—

(1.) To analyze the phenomena of condensation, by laying down the general, physical and mathematical theory of the condenser, which will enable us to determine the loss of motor power caused by the condensation.

(2.) To compare the two systems, viz, condensation by injection, and surface condensation, and to show that the former is greatly superior to the latter.

(3.) To determine in what respects the present injecting condenser is capable of important improvements.

(4.) To prove that the surface condenser is subject to perturbations, which diminish, and may even counterbalance, the advantages of high pressure.

I shall further show that the injecting condenser may be made applicable to high pressure marine engines, as well as to other steam motors, by an important modification, which I shall point out, in the functions of the condenser, and I shall describe the practical means of effecting its application.

(1.) There are two kinds of condensers. In the first the steam is brought directly in contact with the cold condensing water, which mingles inseparably with the condensed water. In the second the condensing water acts upon the steam through an intervening metal, which is a good conductor of heat, and also serves the important purpose of keeping the condensing and condensed waters separate. The former is called the injecting condenser, and is the kind most frequently employed. The latter is called the surface or Hall condenser, and until quite recently had been employed only in certain special engines (ether, chloroform, alcohol engines), which are not yet out of the domain of experiment.

(2.) I shall first proceed to determine a general formula expressing the resistance of the condenser. The act of condensation is not accomplished instantly, but requires a certain length of time. If L represent the stroke of the piston, n L will be that part traversed by the piston while the condensation is in progress. Let

T m be the motor power, or work developed by the steam at each stroke.

T c i be the resistance of the injecting condenser.

T c s be the corresponding resistance of the surface condenser.

T c be the corresponding resistance of a condenser of either system (the general expression of resistance).

T a be the resistance of the air pump.

S be the area of piston of cylinder (in sq. centimeters).

L be the stroke in meters.

E be the part of the stroke during which the steam enters with a full pressure.

P be the pressure (in kil. per sq. cent.) after expansion, and at the instant of opening communication with the condenser.

H be the pressure before expansion.

p be the normal pressure in the condenser ; *i. e.*, the pressure which remains after the condensation is finished (in kilog. per sq. centimeter).

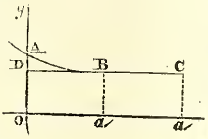
n L be the fraction of the stroke during which the condensation is in progress.

r be the ratio of the capacity v of the condenser (including its connections) to the capacity V of the cylinder (including the volume occupied by the piston and the clearance spaces, thus,

$$r = \frac{\text{condenser}}{\text{cylinder}} = \frac{v}{V}.$$

As soon as the communication is opened

between the cylinder and condenser, the pressure P, corresponding to the volume V, becomes $\frac{\text{P V}}{\text{V} + v}$. At the same instant the pressure p, which corresponds to the volume v, becomes $\frac{p\,v}{\text{V}+v}$. At that instant therefore the pressure in the condenser is $\frac{\text{P V} + p\,v}{\text{V} + v}$, or $\frac{\text{P} + p\,r}{1 + r}$. During the part of the stroke n L this pressure diminishes (at a rate corresponding to the condensation), passing from $\frac{\text{P} + p\,r}{1 + r}$ to p; and during the part $(1 - n)$ L it remains equal to p. Let us represent the successive values of this pressure by the ordinates to a curve. Let $x'' = \text{O}\,a' = \text{L}$, $x' = \text{O}\,a = n\,\text{L}$, $a\,a' = (1 - n)\,\text{L}$, $y\,o = \text{O A} = \frac{\text{P} + \text{P}\,r}{1 + r}$. $y' = a\,\text{B} = a'\,\text{C} = p$.



The portion B C of the line will be straight and parallel to the axis of x; the portion A B will be curved and tangent to B C at the point B.

T c will be represented by the surface S of the piston multiplied by the area A O a' C. The area of D O a' C = L p. To express the other part of the area, we must know the curve A B. In this particular case we may determine it approximately by the Watt indicator, and in this general analysis we shall replace it by an approximation sufficiently accurate, if we use the arc of a parabola, having its vertex at B, passing through A, and having its axis parallel to the axis of y. This arc will in general differ immaterially from the true curve. Hence the part A D B of the total area will be $\frac{1}{3}\,\text{A D} \times \text{B D} = \frac{1}{3}\left(\frac{\text{P} + p\,r}{1 + r} - p\right)\,n\,\text{L}$ $= \frac{1}{3}\,\text{L}\,\frac{\text{P} - p}{1 + r}n$. The total area is then $\frac{1}{3}\,\text{L}\left(\frac{\text{P} - p}{1 + r}\,n + 3\,p\right)$, and the *work* of the condenser is

$$\text{T}\,c = \tfrac{1}{3}\,\text{S L}\left(\frac{\text{P} - p}{1 + r}\,n + 3p\right). \quad (1)$$

This expresses the *resisting work* of the condenser, so far as relates to the counter-pressure alone; and if we simply add the deduction due to the work T a of the air pump, we shall obtain the whole resistance of the apparatus. The formula (1) is applicable to both kinds of condensers, and we shall transform the expression further on, so as to introduce the peculiar elements of both.

(3.) First, however, it is necessary to consider the values, both arbitrary and necessary, which the quantities designated above may take.

T a is a quantity nearly constant, as applied to a given engine, varying very slightly with the quantity of water to be drawn, with the slight counter-pressure of the condenser, and the slight variations of atmospheric pressure. But when the building of an engine is contemplated, it is a matter of no small moment to design it so as to employ the minimum of water, whether the object be to economize it on account of its small supply, or to diminish the effect of T a, which depends for its value chiefly upon the area of the pumping piston.

(4.) The value of P will depend upon the initial pressure H of the steam when it enters the cylinder, and upon the rate of expansion allowed. It is an advantage to give this expansion its greatest practicable amount. L and S being constant in a given engine, the expansion will be limited by the amount of useful effect which can be produced in a given time; and as this latter quantity can be made to vary, its variation should be regulated entirely by the cut-off, which may work automatically or at control of the engineer. But we are of the opinion that, other things being equal, the range of expansion will be extended in proportion as the pressure is increased, and hence the advantage (which is considerable) of employing steam at high pressures.

(5.) The pressure in the condenser passes, as we have said, through different values during the stroke of the piston. For a given value of P, and for a single quantity of water introduced, the condensation will be effected in a time equal to, or less, or greater, than the duration of the stroke of the piston. In the first instance the pressure in the condenser will reach the *normal* value p before the end of the stroke; in the second p will be reached just at the conclusion of the stroke; in the third case the value of p must be increased to p', in order that the normal pressure may be reached during the time of the stroke. We must therefore give to p just the value which the normal pressure has at the instant the stroke is completed. It will be observed that p is the sum of two pressures—the one f due to the steam (watery vapor) which remains normally in the condenser, the other f due to the gases given off by the condensing and feed water, and to the air which may find access by leakage. In an apparatus properly managed and cared for, and built upon correct principles, there ought not to be any leakage. The gases given off by the feed waters of the boilers are insignificant in well managed engines, because that water is drawn from the condenser itself, and has already been freed from the greater part of its gases. We may then proceed to determine f and f'.

In a particular case we might determine f by means of a table of the elastic forces of vapors, and according to the normal temperature of the condenser. But we must note that this temperature is really higher than that of the water taken from it, because the contact of the condensing water and the steam is of short duration, and only partial—the water not being generally in a sufficiently divided state to establish a thermal equilibrium in so short a time. In order to determine it the thermometer should be placed in a part of the condenser opposite the entrance of the steam, and protected from the injected stream. The quantity f being thus obtained, we shall have f' by deducting $p-f$; and the value of p will be given by the manometer of the condenser.

(6.) But it will be advisable to introduce into eq. (1) the value of p as a function of the normal temperature of condensation, θ of the temperature, t of the cold water, and of the volume q of the water resulting from the condensed steam at each stroke of the piston.

We shall then have (according to Southern)—

$$f = A + \left(\frac{B+\theta}{C}\right)^{5.13}; \quad A = 0.0034542 \quad B = 46,278 \quad C = 145.36$$

Also let

$\theta =$ the temperature of the condenser corresponding to the elastic force of the steam f.

$t =$ the temperature of the injected cold water.

$\frac{1}{m} =$ the proportion (in volume) of gas which that water contained.

$Q =$ the volume of cold water theoretically necessary for injection at each stroke of the piston.

$q =$ the volume of water resulting from the condensation of the steam at each stroke.

$$\text{Then, } Q = q\,\frac{650-\theta}{\theta-t}.$$

But in the injecting condenser this quantity Q should be doubled in practice. The volume of gas introduced into the condenser at each stroke of the piston is then (at the pressure of 1 atmosphere)

$$\frac{2\,Q}{m} = \frac{2\,q}{m}\cdot\frac{650-\theta}{\theta-t},$$

at the temperature t, and at the temperature θ of the condenser is $\frac{2\,q}{m}\cdot\frac{650-\theta}{\theta-t}\cdot\frac{274+\theta}{274+t}$

The pressure of this gas is that of the atmosphere, 1.03 kilog. per square centimeter under the volume given above, and becomes, under the volume v of the condenser,

$$f' = \frac{2.06}{m}\cdot\frac{q}{v}\cdot\frac{650-\theta}{\theta-t}\cdot\frac{274+\theta}{274+t},$$

$$\text{Hence, } p = A + \left(\frac{B+\theta}{C}\right)^{5.13} + \frac{2.06}{m}\cdot\frac{q}{v}\cdot\frac{650-\theta}{\theta-t}\cdot\frac{274+\theta}{274+t}\ldots \quad (2)$$

(7.) The quantity n varies in consequence of some circumstances which it is well for us to examine.

The escape of the steam from the cylinder to the condenser, though very rapid on account of the difference of the two pressures, is by no means instantaneous. The connections are always ample, of course, but the opening of the ports is, during a portion of the valve movement, partially obstructed. This becomes apparent on the diagrams by a rounding off of the angles where the piston changes its motion, and by the rapid fall of the pressure just before the instant of cut-off. But in well built injecting condensers this partial cause of retarded condensation may be neglected, especially if the velocity of the piston be not excessive. It must not, however, be neglected in surface condensers, because the condensing surfaces usually consist of tubes of small diameter, among which the steam circulates with some difficulty, especially when it encounters a certain amount of air and other permanent gases.

Secondly, the cold water is introduced in the form of jets more or less divided, offering a certain amount of surface of direct contact to the steam. Water being a poor conductor of heat, an equilibrium takes place almost at the instant of contact of the steam with the water of the jets, and that collected in the bottom of the chamber—the walls of the chamber also taking part in the operation. But all these surfaces are heated by the condensation, and their condensing power correspondingly reduced; and as they are only partially cooled again by succeeding movements, it would appear that their action cannot be instantaneous in destroying the difference between the pressures P and p.

(8.) Let us take the general expression $x = \frac{L}{2}(1 - \cos \tilde{\omega})$ for the space passed over by the piston for any angle $\tilde{\omega}$ described by the rotation of the crank—neglecting the small variations arising from the variable position of the connecting rod. The angular velocity of the crank being constant, $\tilde{\omega} = \tilde{\omega}' \frac{\tau'}{\tau}$; or, taking for the angular unit $\tilde{\omega}' = 180°$, then $\tilde{\omega} = \frac{\tau'}{\tau}$; in which equation τ' = the time corresponding to x, and τ = the time of a whole stroke of the piston. Then

$$x' = \frac{L}{2}\left(1 - \cos \frac{\tau''}{\tau}\right)$$

τ'' being the time corresponding to x', and

$$\frac{x''}{L} = n = \tfrac{1}{2}\left(1 - \cos \frac{\tau''}{\tau}\right).$$

We assume τ' and τ to be expressed in seconds.

Let Φ express the rapidity of the absorption of heat by the condenser, *i. e.*, the quantity absorbed in one second ; then $\tau'' \Phi$ will be the quantity absorbed during the whole process of condensation. The expression for this quantity is D $q\,(650 - \theta)$; D being the density of the water, and assuming D =1, then

$$\tau'' = \frac{q\,(650 - \theta)}{\phi}.$$

Substituting this,

$$n = \tfrac{1}{2}\left[1 - \cos \frac{q\,(650 - \theta)}{\tau\,\phi}\right]$$

Now we may put $\Phi = R\,\phi$, R being a co-efficient < 1, depending partly upon the resistance due to the pressure of air, and partly upon the friction of the steam, whether in the connections of the general condenser, or in the tubes of the surface condenser. ϕ will be composed, first, of heat transmitted through the walls or skin of the condenser, and expressed by

$$a = \kappa\,\tau\,\frac{a' - b}{e} \quad . \quad . \quad . \quad . \quad (3)$$

in which

κ = the co-efficient of conductibility of the walls; that is, the quantity of heat which passes in 1″ of time through one sq. met. of this wall, with an assumed thickness of one millimeter and for a difference of 1° of temperature between the two sides of the wall.

σ = the surface of each of these two sides.

a' = the mean temperature of the inside.

b = the mean temperature of the outside.

Second—There also enters into the value of ϕ the heat β absorbed by the water collected at the bottom of the condenser.

Third—The heat absorbed by the injected cold water.

This last quantity, by far the greatest, will be expressed by $\mu\,\Sigma\,(\Theta - t)$, in which

μ = the exterior conductibility of the water, or the quantity of heat which enters in 1″ of time into one sq. meter of aqueous surface, for a difference of 1° between the temperature of the water and of the steam.

Σ = the surface of the jet in sq. met.

Θ = the mean of the temperatures through which the condenser passes during a stroke of the piston.

t = the maximum temperature of the injected water.

We may then place as the general value of n,

$$n = \tfrac{1}{2}\left\{1 - \cos \frac{q\,(650 - \theta)}{R\,\tau\,[a + \beta + \mu\,\Sigma\,(\Theta - t)]}\right\} \quad (4)$$

(9.) For the sake of brevity let us place

$$M = \frac{2.06}{m} \cdot \frac{650 - \theta}{\theta - t} \cdot \frac{274 + \theta}{274 + t}.$$

also;

$$f = A + \left(\frac{B + \theta}{C}\right)^{5.13}$$

and substituting in eq. (1) these values, and the value of n, as given above,

$$T\,c = \tfrac{1}{3}\,S\,L\left[\left(P - f - M\,\frac{q}{v}\right)\tfrac{1}{2}\,\frac{1}{1+r} \times \left(1 - \cos \frac{q\,(650 - \theta)}{R\,\tau\,[a + \beta + \mu\,\Sigma\,(\Theta - t)]}\right) + 3\left(f + M\,\frac{q}{v}\right)\right] \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

This equation is general and applicable to both kinds of condenser—cancelling the term $\mu\,\Sigma\,(\Theta - t)$ when it is applied to the surface condenser. In the injecting condenser we may also suppress a and β as being inconsiderable compared with $\mu\,\Sigma\,(\Theta - t)$. In reality the external and internal surfaces of this condenser are always incrusted or oxidized, and the latter is also always protected by a tissue of stagnant water—circumstances which diminish considerably the conducting power of the walls. It is otherwise plain that β is a very inconsiderable quantity, because the warm water in the bottom of the condenser exposes to the steam only its upper or warmer surface, while its interior conducting power is very small.

For the injecting condenser then we may place

$$T c i = \tfrac{1}{3} S L \left[\left(P - f - M \frac{q}{v} \right) \tfrac{1}{2} \cdot \frac{1}{1+r} \times \left(1 - \cos \frac{q(650-\theta)}{\tau \mu \Sigma (\Theta - t)} \right) + 3 \left(f + M \frac{q}{v} \right) \right] \quad (6)$$

We have assumed $R = 1$. We shall also have occasion to equate the value of $T c i$ in the forms,

$$T c i = \tfrac{1}{3} S L \left[(P - p) \frac{1}{1+r} \cdot \tfrac{1}{2} \left(1 - \cos. \frac{q(650-\theta)}{\tau \mu \Sigma (\Theta - t)} \right) + 3 p \right] \quad . \quad . \quad . \quad (7)$$

$$T c i = \tfrac{1}{3} S L \left[\frac{P - p}{1 + r} n + 3 p \right] \quad . \quad . \quad (8)$$

We will put this expression into another form, which will show more clearly the influence of the surface Σ. Let Σ' be such a value of this surface that the duration of the condensation may equal that of a stroke of the piston, or so that $n = 1$. We shall then have in eq. (4), in which a and β are suppressed and $R = 1$,

$$n = \tfrac{1}{2} \left[1 - \cos \frac{q(650-\theta)}{\tau \mu \Sigma' (\Theta - t)} \right] = 1$$

$$\text{whence } \cos \frac{q(650-\theta)}{\tau \mu \Sigma' (\Theta - t)} = -1.$$

in other words

$$\text{arc } (\cos = -1) = \frac{q(650-\theta)}{\tau \mu \Sigma' (\Theta - t)} \text{ or,}$$

$$1 = \frac{q(650-\theta)}{\tau \mu \Sigma' (\Theta - t)}. \quad . \quad . \quad (9)$$

Deducting from this equation the value of q and substituting it in eq. (7), we have

$$T c i = \tfrac{1}{3} S L \left[(P - p) \frac{1}{1+r} \cdot \tfrac{1}{2} \left(1 - \cos \frac{\Sigma'}{\Sigma} \right) + 3 p \right]. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

It is obvious that this formula is applicable only for values of Σ greater than, or at least equal to, Σ'; for if we assume a value for Σ lower than Σ', it would be equivalent to supposing that the condensation would take place at a normal temperature θ' higher than θ.

(10.) It may be remarked that all these expressions of work consist of two elements; one expressed by the first term, which is the work due to the retardation of the condensation, or its duration, and the other due to the normal counter-pressure. I purpose discussing these quantities separately, beginning with the counter-pressure.

(11.) In principle there is no maximum rate of injection. On the subject of normal counter-pressure there is a prevalent opinion that the volume of gases introduced increasing with the quantity of water, there is, for each kind of water and condenser, a rate of injection to which there corresponds a minimum counter-pressure. This is true, but it is the result of imperfections in condensers, and not of injecting condensation as a principle, as we shall prove.

We have taken (§ 6)

$$p = A + \frac{(B + \theta)^{5.13}}{C} + f';$$

f' being the part of the pressure due to the gases brought by the condensing water. Eq. (2) expresses the value of p in ordinary condensers, where, as we have already remarked, it is necessary to inject about twice the quantity theoretically necessary, $\left(Q = q \frac{650 - \theta}{\theta - t} \right)$ on account of the imperfect mixture of the water with the steam. If we suppose the mixture to be perfect, then the equation

$$Q = q \frac{650 - \theta}{\theta - t} \quad . \quad . \quad . (2a)$$

expresses the quantity effectively injected, and the temperature, and may be used to determine either one of these quantities in terms of the other.

On this supposition, in place of eq. (2), we have

$$p = A + \left(\frac{B + \theta}{C} \right)^{5.13} + \frac{1.03}{m} \cdot \frac{q}{v} \cdot \frac{650 - \theta}{\theta - t},$$

supposing the factor $\frac{274 - \theta}{274 - t} = 1$, which is approximately true in practice.

Replacing θ by its value deduced from the above

$$\theta = \frac{650 + t \frac{Q}{q}}{1 + \frac{Q}{q}}, \quad . \quad . \quad . \quad (2b)$$

we shall have

$$p = A + \left[\frac{B}{C} + \frac{650 + t \frac{Q}{q}}{C \left(1 + \frac{Q}{q} \right)} \right]^{5.13} + \frac{1.03}{m} \cdot \frac{Q}{v}$$

Differentiating and placing $\frac{d p}{d Q} = 0$,

$$\frac{d p}{d Q} = 0 = -5.13 \left[\frac{B}{C} + \frac{650 + t \frac{Q}{q}}{C \left(1 + \frac{Q}{q} \right)} \right]^{4.13} \cdot \frac{650 - t}{C \left(1 + \frac{Q}{q} \right)^2} \cdot \frac{1}{q} + \frac{1.03}{m} \cdot \frac{1}{v} \quad . \quad (2c)$$

It is from this equation that we may deduce the value of Q which will give the minimum value of p. We shall proceed, then, to show that, within practical limits, there is no value of Q which will satisfy this equation.

1st. It is impracticable to condense beyond 100°, and it is rarely advantageous to condense below 20°, which corresponds to a tension of 1.70 centimeters of mercury, which should be at least sufficient to raise the valves of the air and water pump. According to eq. (2 b) the values of $\frac{Q}{q}$ corresponding to 100° and 20° respectively, are (supposing $t = 10°$) 6.1 and 63.

2d. The value of m is hardly greater than $\frac{1}{20}$, and we will therefore take it at that value.

3d. q depends upon the pressure H of the steam before cut-off, and the quantity E, the part of the stroke during which steam is admitted. H varies between 1 and 10 atmospheres, and E between $\frac{1}{15}$ and $\frac{1}{2}$. Hence we have $q = \frac{u}{\triangle}$; (u being the volume of steam introduced, and $\triangle$ the specific volume of its resultant water at the pressure H.

For H = 1 atmos. and E = $\frac{1}{2}$ we find

$$u = \frac{V}{2} \text{ and } \triangle = 1700;$$

whence

$$q = \frac{V}{1700 \times 2}$$

For H = 8 atmos. and E = $\frac{1}{15}$, we find

$$u = \frac{V}{15} \text{ and } \triangle = 254;$$

whence

$$q = \frac{V}{254 \times 15}.$$

4th. The volume of the condenser v varies between $\frac{V}{5}$ and V. Introducing these values into eq. (2 c), as well as the values of B and C.

For $\theta = 100°$, or $\frac{Q}{q} = 6.1$,

we find for H = 8 atmos.

$$-5.13\left[0.33 + \frac{650+61}{145 \times 7.1}\right]^{4.13} + \frac{640}{145 \times 7.1^2} \times \frac{254 \times 15}{V} + \frac{1}{V} 1.03 \times 20 = -1714\frac{1}{V} + 20.6\,\frac{1}{V};$$

a result with a *negative sign.*

For $\theta = 20°$ or $\frac{Q}{q} = 63$,

we find for H = 8 atmos.

$$-5.13\left[0.33 + \frac{650+630}{145 \times 64}\right]^{4.13} \times \frac{640}{145 \times 64^2} \times \frac{254 \times 15}{V} \times \frac{1}{V} 1.03 \times 20 = -171.14\,\frac{1}{V} + 20.6\,\frac{1}{V},$$

a result also with a negative sign.

It is clear that the results will continue to be negative in the case where the expansion E is $\frac{1}{2}$, and *à fortiori* in any case where it is expressed by a smaller fraction between $\frac{1}{2}$ and $\frac{1}{15}$. It is also plain that the results will be negative for pressures H lower than 8 atmospheres, since, in the negative term, which alone is a function of the pressure, the factor 254 will be replaced by numbers exceeding that factor, in proportion as H diminishes. Hence the equation (2 c) admits of no roots for values of the variable corresponding to normal temperatures between 20 and 100 degrees; in other words, there is no minimum of pressure between these limits. We therefore infer that we may advantageously bring the normal temperature θ of the condenser as near to that of the cold water as the circumstances of each particular case will warrant; regard. being had to the manner of disposing of the water. The vacuum has then no limit except the residuary force necessary to lift the valves of the air and water pumps. It will be readily seen, from a particular example, that with the cold water at 10° to 15° (since we can practically obtain only a vacuum indicated by 6 to 7 cent. of mercury, let $\theta = 45°$), we can, by suitably increasing the rate of injection, and supposing that we can always obtain a complete mixture of water and steam—we can, I say, reduce θ to 20° or 25°, and therefore reduce P to 2.8 or 2. cent. of mercury.

I conclude, then, that that portion of the work of the injecting condenser due to the normal counter-pressure p S L can be reduced from .093 S L, corresponding to a vacuum of 7 cent. of mercury, to .027 S L corresponding to a vacuum of 2 cent., making a reduction of say 71 per cent.

(12.) In formula (7) the first term is always positive, since P is always greater than p; otherwise the piston would be stopped before the end of the stroke; or if it continued its motion by virtue of the inertia of the machinery, the living force of the latter would be diminished, so as to interfere with the regularity of the movement of the engine, and without any compensating advantage. This shows that the cut-off may be carried too far to allow of an efficient condensation. Hence, other things being equal, if we make r vary, the work T c i will diminish proportionally to $(1+r)$. Again, $\cos \frac{q\,(650-\theta)}{\tau\,\mu\,\Sigma\,(\Theta-t)}$ increases from -1 to $+1$, according as τ and Σ, or either of these two, increase. It appears from eq. (17), which follows, that the term expressing the work due to the retard of the condensation is in the inverse ratios of τ^2 and Σ^2. Hence the inferences, that it is advantageous to increase as much as practicable the vacuum space of the condenser; to give the injected jet of water the largest possible surface Σ; and to increase as much as possible the length of stroke of the piston.

(13.) The first of these conditions seems to have escaped the attention of engineers and builders. The only point upon which they have been preoccupied in this particular is to increase in some measure the capacity of the condenser, with the object of diminishing the back pressure of the gases; persuaded, no doubt, that the condensation is instantaneous. But eq. (6) shows that T c i varies not only by the quantity $M\frac{q}{v}$ relative to the pressure of the gases, but still more by the factor $(1+r)$. In fact the rule generally adopted for the capacity of the condenser, is to make it between $\frac{1}{4}$ and $\frac{1}{5}$ that of the cylinder for single acting engines, and $\frac{1}{8}$ for double acting.

M. Farcot has deviated from this rule in the engines of the Imperial manufactory of Gros-Coillon, which have a condenser equal to the cylinder in capacity. We believe we can recommend his variation. We will show the importance by an example. Take a particular case, where P = 1 at. = 1.03 k.; $p = 0.1$ at. = .103 k. Take formula (8), where $n = 1$. Substituting, we have

$$T\,c\,i = S\,L = \left(\frac{.309}{1+r} + .103\right)$$

Make successively $r = \frac{1}{8}, \frac{1}{5}, 1, 2.$ Then

$$T\,c\,i^{(\frac{1}{8})} = .377\ S\ L$$

$$T\,c\,i^{(\frac{1}{5})} = .360\ S\ L$$

$$T\,c\,i^{(1)} = .257\ S\ L$$

$$T\,c\,i^{(2)} = .206\ S\ L$$

and substituting

$$\frac{T^{(\frac{1}{8})} - T^{(1)}}{T^{(\frac{1}{8})}} = \frac{120}{377} = .32.$$

$$\frac{T^{(\frac{1}{8})} - T^{(2)}}{T^{(\frac{1}{8})}} = \frac{171}{377} = .45.$$

$$\frac{T^{(\frac{1}{5})} - T^{(1)}}{(T^{(\frac{1}{5})}} = \frac{103}{360} = .28.$$

$$\frac{T^{(\frac{1}{5})} - T^{(2)}}{T^{(\frac{1}{5})}} = \frac{154}{360} = .42.$$

Hence, in an engine expanding till the pressures becomes 1 atmosphere, condensing at 0.1 at., and where the duration of the condensation equals the time of a stroke of the piston,

1st. The condenser having a vacuum capacity of $\frac{1}{8}$ the volume of the cylinder, ($r = \frac{1}{8}$), if it be replaced by another equal to the volume of the cylinder ($r = 1$), then the work T c i will diminish 32 per cent. If replaced by one double the volume of the cylinder, T c i will diminish 45 per cent.

2d. The condenser having $\frac{1}{5}$ the volume of the cylinder, if the same substitutions are made, T c i will diminish in the first case 28 per cent, and in the second 42 per cent.

(14.) As to the second inference (No. 12), no importance has heretofore attached to it, though it possesses a great deal. The water is brought into a receiver placed beside the condenser, whence it flows into the latter by means of atmospheric pressure through a common nozzle, with no provision, however poor, for dividing the jet. It will be well to examine the influence of Σ upon the work of the condenser.

Let P = 1.03 k., $p = .103$ k., $r = \frac{1}{5}$, and taking eq. (10),

$$T\,c\,i = S\,L\left[.128\left(1 - \cos\frac{\Sigma'}{\Sigma}\right) + .103\right]$$

it will be seen that, if Σ be only slightly increased, T c i will be only insensibly diminished. This last remark explains why we obtain no improvement in the vacuum, practically, by increasing the admission of water beyond a certain degree; for though we increase the admission of water, we increase the surface of the jet very inconsiderably, and even this slight increase is counterbalanced, or even more, by the increase in the quantity of gases brought in. But suppose that, by means which I shall indicate, we could double, triple, quadruple, centuple Σ; the differences between the values of $T\,c\,i$ would become very perceptible. For instance, make successively $\Sigma = \Sigma'$; $10\ \Sigma'$; $100\ \Sigma$; then

$$\overset{(1)}{T\,c\,i} = S\,L\,[.128.2 + .103] = .359\ S\,L$$

$$\overset{(10)}{T\,c\,i} = .109\ S\,L$$

$$\overset{(100)}{T\,c\,i} = .1031\ S\,L,$$

and

$$\frac{\overset{(1)}{T\,c\,i} - \overset{(10)}{T\,c\,i}}{\overset{(1)}{T\,c\,i}} = \frac{.250}{.359} = .69.$$

$$\frac{\overset{(1)}{T\,c\,i} - \overset{(100)}{T\,c\,i}}{\overset{(1)}{T\,c\,i}} = \frac{.2559}{.359} = .71.$$

Hence, having an engine where the duration of the condensation equals the time of the stroke of the piston, where $\Sigma = \Sigma'$ or $n = 1$, if we increase tenfold the surface of the jet, the work will diminish 69 per cent, and if we increase it a hundredfold, the work will diminish 71 per cent.

(15.) Let us now inquire how the desired increase in the surface of the jet may be obtained, and within what limits it may be properly increased.

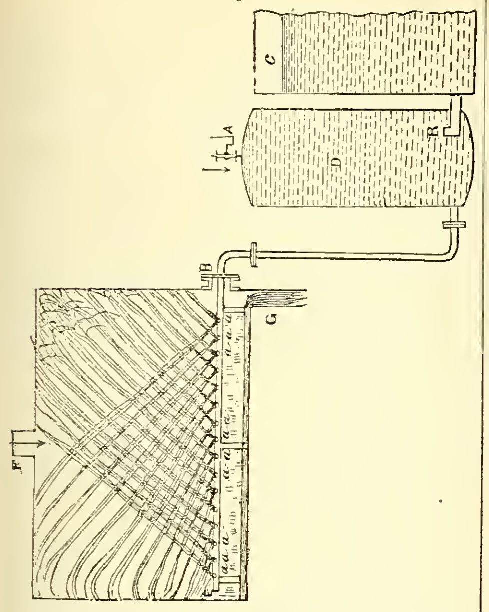
M. Sanial du Fay, a naval engineer, has devised a method of "pulverizing" the water, or reducing it to the form of spray, thus giving it a great amount of surface. This method consists in forcing the water through two converging nozzles, so that the two streams collide a short distance from the points of emergence, the result being a minute division of the water. The minuteness of the division increases with the pressure under which the water is forced. By this means a litre of water can be given 600 square meters of surface. The water enters the condenser in this comminuted condition, and the stream, mingling with it, obtains a great surface of contact—as it were, particle with particle. There results a sudden and intimate mixture, a very rapid condensation, and a perfect equilibrium of temperature between the water of the condenser (consisting of injected water, and water of condensation) and the normal vapor of the condenser.

(16.) Besides the advantage of rapid condensation, we also have the power of diminishing the actual rate of injection. Let us examine this.

1st. The quantity of water at the temperature t necessary theoretically to condense to the temperature θ is, for each stroke, $Q = q\ \frac{650 - \theta}{\theta - t}$. Generally the quantity of water required in practice varies between 1.75 Q and 2 Q. This is due to the fact that a considerable portion of the water escapes contact with the steam, and has no effect upon the condensation. Practically, on the one hand, the surface Σ of the jet is relatively small, and is but little increased by opening wider the injection valve. On the other hand, the water is kept flowing in a constant stream, while it should, on principle, diminish as the condensation goes on, and terminate with it. Hence it happens that the water issues from the condenser at a temperature below θ, and the condensation occupies the whole stroke of the piston. This is shown by the diagrams when they are drawn with care, and by the aid of an indicator sufficiently sensitive. To approximate the rate of injection to the theoretical rate there is requisite, not merely a rapid and intimate mixture of water and steam, but also an intermittent injection, lasting only during the time absolutely necessary for condensation.

With this view I propose the following arrangement. The cold water cistern, instead of being open, is to be closed and put into communication intermittently, at each stroke of the piston, with steam which surrounds the cylinder. This communication should last a little longer than the time requisite for condensation. The flow of the water will be effected by the pressure of the steam, and will cease the moment the communication is intercepted. Fig. 2 will give the idea substantially. D is the cistern, subject to intermittent pressure; A, a valve worked by the rod of the slide valve; E, injecting condenser; F, steam port opening into condenser; G, communication with air and water pump; a, Du Fay nozzles for comminuting the water; they are fixed in a copper pipe, which can be easily withdrawn in case of obstruction, and another replaced through the hole B; C, reservoir of cold water; R, check valve between the cistern and reservoir. When the valve A is open, the check valve R shuts; when it closes, R

Fig. 2.



is opened by atmospheric pressure, and the water expended from D is resupplied automatically by the reservoir C. By means of such an arrangement the actual rate of injection may be diminished so as not to exceed one-tenth the theoretical rate, which is, in effect, the use of water amounting to 1.1 Q in place of 1.75 Q — an economy of $\frac{.65}{1.75}$ or .37.

This economy may, in some cases, be a matter of no small consequence; indeed it may become highly important when water is in limited supply, or has to be pumped from a great depth, or when it is necessary to allow a high temperature in the condenser and consequent strong back pressure, or even to otherwise abandon the condenser altogether.

2d. In a case where this economy of water can be realized, instead of employing it to reduce the normal temperature θ, and consequently the back pressure of the condenser, we may reduce in the same proportion, viz, 37 per cent the volume of the air pump, and thus diminish sensibly the resisting work of this member. The work T a of this pump is

$$T\, a = O + (1.03 - p')\, s\, l;$$

an expression in which O is the work due to the exhausting of the water and air, and to friction; s, the area of piston in sq. cent.; l; the stroke; p, the mean pressure in the condenser during a stroke of the piston. Keeping in view the preceding, s may be replaced by

$$s' = s\,(1 - .37) = .63\, s$$

and substituting

$$T\, a = O + (1.03 - p')\, .63\, s\, l.$$

Allowing that O remains the same—a supposition not favorable to our case—then

$$\frac{T\, a - T'\, a}{T\, a - O} = 1 - .63 = .37.$$

(17.) The third condition mentioned in (§ 12) with reference to the duration of the stroke of the piston, seems to have received no attention in the various projected engines. This element of the problem has always been made subordinate to considerations having no reference to the development of power. This will be seen by the following tables, taken from examples given in the work of M. Gaudry, Traité des Machines.

It appears by these tables that the duration of the stroke varies between 0″.375 and 1″.200, and without any relation to the elements of motor power (pressure, diameter, and velocity of piston). It appears that it has been determined only after the diameter of the wheels or the pitch of the screw, with the view to obtaining a given

velocity for the moving apparatus. In engines already constructed this duration can be modified only by changing the velocity of the piston, and this by diminishing or increasing the admission of steam. Under all circumstances where the resistance to be overcome will allow of a diminution of this velocity it will be advantageous to make it. But when we contemplate the construction of an engine, and observe that we can vary within certain limits the diameter of wheels and screws, the angular velocities, and the rate of gearing, we may realize the advantages of a long stroke of the piston. For example, the vessels Encounter, Niger, Arrogant, Termagant, whose strokes are respectively .375, .400, .500, .833 seconds, might have been so constructed as to make but 25 turns per minute, like the Napoleon, by means of suitable gearing or otherwise.

We may put eq. (7) under the form

$$T c i = \frac{1}{3} S L \left[(P - p)\frac{1}{1+r} \cdot \frac{q^2 (650-\theta)^2}{4 \tau^2 \mu^2 \Sigma^2 (\Theta - t)^2} + 3 p \right];$$

replacing the cosine by its value in terms of the arc, and stopping at the second term of the series, which gives this value. It will be seen that, all other things being equal, if we can vary the time of the stroke of the piston, the portion of the work due to the retardation of the condensation will diminish proportionally to the square of this time.

(18.) Resuming the principal results furnished by the discussions of the formulas relative to the injecting condenser, we make the following deductions.

1st. There is no maximum rate of injection. The vacuum of the condenser has no other limit than the weight of the valves of the air pump, and the portion of the work due to the normal counter-pressure can be reduced about 71 per cent.

2d. There is an advantage in increasing the vacuum space of the injecting condenser. By increasing it five times, the work due to the retardation of condensation will be diminished 28 per cent; increasing it ten times, it will be reduced 42 per cent.

3d. By injecting the water in a state of fine division, this same work may be reduced 71 per cent. If the second and third reductions are realized at the same time, their combined effect will be (calling $T r$ the work due to the retardation), $T r (1 - .42)(1 - .71) = 17\ T r$.

The total reduction then is $\frac{T r (1 - .17)}{T r} = 83$, or 83 per cent.

4th. The actual rate of injection may be reduced about 37 per cent.

5th. It is advantageous to make the time of the stroke of the piston as long as may be consistent with the work to be done.

(19.) To show the importance of the advantages resulting from the reductions of work just mentioned, it only remains to determine, by some examples, the relation between the resisting work of the condenser and the developed motor power. I shall do this, theoretically, by means of some formulæ I have obtained, and practically by the use of diagrams. drawn with great care by an ingenious contrivance made by M. Farcot. These diagrams were constructed by M. Demondiser, chief engineer of the government manufactories, figs. 3 to 11.

We may observe that, in each diagram the curve determines three areas, viz, the

Fig. 3.

area *a b c d h i*, fig. 3, which represents the developed power per sq. cent. of surface of the piston; that is, the quantity

$$\frac{\mathrm{T}\,m}{\mathrm{S}} = \mathrm{H\ E}\left(1+l\frac{\mathrm{L}}{\mathrm{E}}\right);$$

the area *f g h i* representing the portion of the resisting work of the condenser due to the normal counter-pressure *p*, which I shall designate by T *p*; that is, the quantity

$$\frac{\mathrm{T}\,p}{\mathrm{S}} = p\,\mathrm{L};$$

and the area *d e f g* representing the other part of the work of the condenser due to the retardation of condensation, which I shall designate by T *r*; that is, the quantity

$$\frac{\mathrm{T}\,r}{\mathrm{S}} = \tfrac{1}{3}\,\mathrm{L}.\frac{\mathrm{P}-p}{1+r}\,n.$$

I give in the following table the values of $\frac{\mathrm{T}\,r}{\mathrm{T}\,m}$, $\frac{\mathrm{T}\,p}{\mathrm{T}\,m}$, $\frac{\mathrm{T}\,c\,i}{\mathrm{T}\,m}$, deduced separately from the aforementioned diagrams, from eq. (8), and also eq. (10), to a condenser modified conformably to the consideration in § 12–16.

The engine which furnished these diagrams made 29 revolutions per minute, and its condenser had a vacuum space one-fifth the capacity of the cylinder. The valves had but a very slight lead. In the diagrams the line of perfect vacuum was determined by the pressure *p* observed by the manometer of the condenser, and the portion of the initial ordinate below the atmospheric line. The values of *n*, introduced into eq. (8), were determined by the diagrams. As there was some uncertainty about the true position of the point of contact of the arc of the parabola with the line parallel to the atmospheric line, there resulted also some indecision as to the true values of $\frac{\mathrm{T}\,r}{\mathrm{T}\,m}$, and consequently of $\frac{\mathrm{T}\,c\,i}{\mathrm{T}\,m}$ deduced from that formula. It will be readily understood that the values deduced from the diagrams are still less precise. There should be, then, some differences in the results from the diagrams and those deduced from the formulæ. But they approximate sufficiently to allow the conclusion that $\frac{\mathrm{T}\,c\,i}{\mathrm{T}\,m}$ ranges between 12 and 14 per cent, or a mean of 13 per cent, in which $\frac{\mathrm{T}\,r}{\mathrm{T}\,m}$ figures for seven per cent, and $\frac{\mathrm{T}\,p}{\mathrm{T}\,m}$ for six per cent.

It will be seen that, in the actual condenser, $\frac{T\,c\,i}{T\,m}$ varies between .118 m. and .145 m., the mean being .130 m. This ratio, in the modified condenser, gives a mean of .033 m., being an economy of 6.5 per cent of developed power, not including the economy in the working of the air pump.

(To be continued.)

MALLEABLE CAST IRON.

Translated from "Le Génie Industriel."

For the production of this material most of the German founders use first fusion pig, free from sulphur and phosphorus, or Scotch pig. Styria also furnishes a suitable iron, which can be used only in the north of Germany, however, on account of the expense of transportation and high duties. On account of the competition of wrought iron, great cheapness is very essential to its sale.

The makers keep secret the brand or grade of iron which they employ, but it is well understood that the brands are not the same in different establishments. The iron is melted in plumbago crucibles, holding about 30 kilog. They are covered with porcelain lids, to keep out impurities and cinders which reduce the high heat requisite for the process. The fire, in which the crucibles are placed, is from .630 m. to .940 m. square, and is surrounded with bricks of porcelain earth. The use of blast is not advantageous, since the economy of time is offset by a greater consumption of coke. The natural draught of the chimney is sufficient when the furnace is properly constructed. As we have said, an essential condition of success is a high heat at the moment of pouring. Practice enables the founder to estimate the heat of the furnace, and he recognizes the precise moment by plunging a bar of red hot iron into the crucible, from which, upon being withdrawn, the metal flies off in sparks. The crucibles are raised with tongs, with curved jaws, and the pouring is done with all possible promptitude—the surface being first cleaned.

By cementation the casting acquires the properties of wrought iron, having some analogy to steel. The operation consists in subjecting the castings to a prolonged red heat, in a bath of pulverized red hematite. They are arranged in boxes of cast iron called muffles. It would seem that the cylindrical form ought to be most advantageous for the boxes, but practically they are simply square, and with covers which should keep out entirely the least access of air.

In arranging the castings in the boxes they are placed in layers alternately with layers of hematite. The cementing furnace is very simple. The grate is in front, and the draft of the chimney carries the hot air around the boxes. The heat should be conducted with care, starting rather vigorously, in order to reach quickly the desired temperature; then supplying the furnace at regular intervals. The cementation lasts three, four and five days, according to the size of the pieces. A charge is about 350 to 450 kilog. of castings. In arranging the charges large pieces should not be mingled with small, and those muffles containing the larger pieces should be placed in the furnace first. On the other hand the smaller objects are placed on the sole of the furnace. Without these precautions many pieces may be burned, or badly decarburized—the latter becoming something intermediate between iron and steel. When the operation is deemed complete, the fire is allowed to fall, but the furnace is not uncharged until it has gradually cooled. Practice plays an important part in the management of the firing, as the temperature can be judged of only after prolonged experience. Next to the fuel, the greatest expense is the cementing boxes, which are often serviceable only for a single operation.

THE PENNSYLVANIA STEEL WORKS.—These works are producing eight heats of five tons each in one "turn" of twelve hours. This is remarkably fast working, and proves the excellence of the machinery and of the management. The entire eight heats of iron are melted in one charge of the cupola, as improved by Mr. Pearse.

AMERICAN RAILWAYS.

AN ENGLISH VIEW OF THEIR MERITS AND DEFECTS.

From the correspondence of "Engineering."

In the mechanical construction of American rolling stock the bogie plays a most conspicuous part, and is the chief feature of difference between our own practice and that of American engineers. In America its adoption is universal, whilst in this country, in actual practice, it is very little known. There must, of course, be some substantial reason for so great a difference between the practice of two countries so intimately connected.

In the first place, then, the permanent way in America is generally understood to be inferior to our own, and on this point I think very little doubt can exist. The section of rail is usually considerably lighter than with us, and is out of all proportion to the loads it has to carry. The roads are scantily ballasted, and the use of ballast at all is the exception, and not the rule. Much has also been said about the inferior quality of the rails sent to America, but I would venture to say the rails are "more sinned against than sinning," as I shall presently show.

Those who have not had an opportunity of examining the permanent way can form no idea of the rough character it presents. The rails are laminated, bent, crushed, and out of line to an extent entirely unknown in this country. The "fishing" of the joints is also done in a very inferior manner, and there are thousands of miles laid without the joints being fished at all. On one line, where I was detained owing to a goods train being off the track—the result of a broken rail—I took the opportunity of noting the inequalities of the road, and measured the distances the rails had parted asunder at some of the joints; I found in many places the gaps to vary from 1 in. to 3½ in., and the ends of some of the rails thus separated were off the sleepers altogether. The breaking of the rail in question, therefore, ceased to be a matter of surprise. In winter the ground is frozen, for months together, almost as hard as granite, and, practically, during this time no repairs can be done to the road; to make the matter still worse, in freezing it often happens that one rail is elevated 6 in. or 7 in. above the level of the other. These "frost-blisters," so called, are of frequent occurrence, and the unevenness of the line is a source of great trouble and danger.

Some idea may be formed from this of the difference between the American permanent way and our own. It is to such roads as I have described that American engineers have had to adapt their rolling stock, and for them the bogie is an *absolute necessity*, as it enables a carriage to pass over such roads as I have described with less oscillation, vibration, or jolting than is experienced in the railway carriages in this country.

It is only justice, however, to say here that, with increased capital and other favorable circumstances, many of the American lines are being gradually reconstructed and the permanent way made generally equal, and, in some respects, superior to our own; rails of heavier and better sections are being laid down, and steel rails, with steel fish-plates, of greater length than ours, are being largely introduced.

It may, therefore, be worth while to consider if the Americans can construct carriages to pass smoothly over rough roads, whether it be not possible for English engineers to construct stock which, at all events, will run with some degree of comfort over lines which are incomparably superior. The chief difference between the two is, that in the American arrangement, all, or at least the greatest part, of the motion arising from the irregularities of the road is absorbed by the bogie, and not transmitted to the body of the carriage, whilst with us every unevenness in the road is at once communicated to the body of the carriage, the result being that our carriages oscillate at times to a frightful extent, which not only unpleasantly affects the passengers, but is a source of considerable extra expense to the railway companies, for the carriages require to be much heavier than would otherwise be necessary, to withstand the shocks caused by the whole weight of the carriage being thrown violently from one side to the other; the flange friction and also the friction on the ends of the journals is much increased, and the damage to the tyres and permanent way consequently much greater.

It is often a matter of wonder why omnibuses traveling over roads which for evenness bear no comparison to a railway should be so much lighter in proportion to the load they carry. Put hornplates on an omnibus, and you will soon shake it to pieces, and no passenger would ride in it a second time. In an omnibus, however, the irregularities of the road are absorbed by the springs, and not transmitted to the body of the vehicle, and why should not the same principle be carried out in railway practice? Some time ago Mr. Attock, the carriage superintendent of the Great Eastern Railway, successfully interposed india-rubber blocks between the body of the carriage and the frame, in order to prevent the noise being transmitted; the arrangement having also other advantages. The comfort to passengers was found to be so great from this simple introduction that most of our railway companies immediately adopted it, and few carriages are now constructed without the india-rubber blocks. If this principle were carried a little further it would be comparatively easy, not only to prevent the transmission of sound, but also of violent motion arising from inequalities of the road, and the principle embodied in the swing bogie of America would accomplish this, and might easily be adapted to the existing rolling stock.

Having said so much in reference to the principle and utility of the bogie, I may proceed to another distinctive feature in American rolling stock—the chilled cast-iron wheel. The Americans are perfectly familiar with the construction of our carriages, wagons, and locomotives, and the best English examples have been tried on their lines of railway. I saw in the shops of several railway companies numbers of English-made wheels, both wrought iron and wood; some of these had been tried, but very soon broke up, and were frequently the cause of accidents.

However anxious American engineers are to adopt the best arrangements of their own or other countries, we have not been able to offer them wheels at all approaching in strength, durability, and cheapness to their cast-iron chilled wheels.

It was shown both in a recent paper* and during the discussion which followed upon it, how much stronger, cheaper, lighter, and enduring these wheels as manufactured in America (and also on the Continent, where they are largely used) are to our own. Since the Americans have paid us the compliment of trying varieties of wheels manufactured in this country, we might return the compliment, and see how far their wheels would be valuable to us here. One of our most enterprising locomotive super-

*Read before the Institute of Civil Engineers.

intendents, Mr. William Adams, has already made an experiment with them, and in reply to an inquiry as to the result, says, that after running them for a considerable length of time under the bogie of one of his heavy engines, he could see no traces of wear at all, and that the surface in contact with the rail was simply polished.

The American wheels are made from the best cold blast charcoal iron, the strength of which is exceedingly great, as may be judged from their test bars standing a tensile strain of 18 to 21 tons per square inch of section; and not only is the tensile strength great, but their tenacity is equally striking. In breaking the pigs I have seen them bend to a very visible extent before separating. Scotch iron in one or two instances has been attempted, mixed with superior American iron, but without success, and all such admixtures are regarded with extreme suspicion, and are only attempted by inexperienced or unprincipled manufacturers. It is worthy of remark that even among the better class of charcoal irons there is almost as much difficulty in obtaining suitable material (with the requisite chilling and other properties) for these wheels, as there is in selecting suitable material for good Bessemer steel. In America, out of a considerable number of generally excellent irons there are not more than half a dozen which have obtained a special reputation for this class of work, among them the Salisbury, the Richmond, and more recently, and with remarkable success, the Acadian charcoal iron, which, notwithstanding the very high duty of nearly £2 per ton, has been imported from Nova Scotia for the manufacture of chilled wheels by Messrs. Whitney and Sons, of Philadelphia.

In Germany, too, where these wheels are greatly in vogue, and where their manufacture has been conducted with special skill, the range of selection of really suitable irons is comparatively small. The cost of such iron ranges from £6 10s. to £7 10s., or even more, per ton in the States, and the price of wheels 2 ft. 9 in. diameter, weighing from 400 to 550 lb. ranges from £2 15s. to £3 7s. 6d. per wheel or an average of about £14 to £14 10s. per ton. The distances travelled by these wheels have been variously stated, but the average may be safely taken as from 100,000 to 150,000 miles. I may just mention that the wheels are not keyed on, but simply forced on by hydraulic pressure, varying from 20 to 30 tons. There is nothing peculiar about the axles employed, but the axle-box is simple and convenient in construction. On many lines the bearing is formed by running white metal into a brass frame, which is found to be much more economical than brass alone. The distance these bearings will run is from 50,000 to 55,000 miles, and afterwards they are again lined up. The journals are lubricated with crude surface rock oil from the wells of Pennsylvania, the cost of which is only 6d. per gallon; in England we pay from 3s. to 4s. 6d. per gallon.

It is very pleasing to note the efforts made by all the railway companies in America to secure the greatest amount of comfort to the passengers. The subject of ventilation has occupied considerable attention, and ingenious contrivances for effecting this most desirable object are very numerous and interesting. It is a very easy matter by opening a window to admit a rush of air into a compartment, as many of us know to our cost, and it is very uncomfortable to be stifled by having the windows closed altogether; between the two—in this country—we have very little alternative; there are certainly what are termed ventilators over the doors, but they are all but useless, not being constructed on any correct principle for the proper circulation of air.

Now, the Americans have a very simple plan for exhausting or drawing the impure atmosphere out of their carriages, which is the principal difficulty experienced in all attempts at ventilation. On one occasion, whilst traveling in a sleeping car, I felt a strong inclination to smoke a cigar; I asked the attendant if it were permitted, and was informed that such a thing was never allowed; but, seeing that I was an Englishman—and with that desire which, I must say, evinces itself at every turn to show attention to our countrymen—he said: "Though it is not allowed, Sir, I will fix you up so that you can smoke your cigar and no one shall know. I was curious to see how this was to be done, as there were passengers sleeping on every side who would certainly have complained had they perceived anything so unusual. ' Presently he appeared with a small flat board about 7 in. wide and 13 or 14 in. long. "This, Sir, is the ventilator, which I shall put in the window, and you can then smoke as much as you like." He then opened the window, and inserted the board so that it projected at right angles to the carriage-body, immediately causing a strong outward current of air which took away the smoke. The principle of it is easily seen: the board causes a rush of air in front of the window, to the distance it is projected, and a vacuum is thus created on the other side of the ventilator, and the air exhausted from the carriage. With this simple contrivance—and the same principle is carried out in various ways by the Americans—for exhausting the foul air, and by admitting the pure through a considerable area of fine wire-gauze, either in single sheet or a double, placed so as to leave a space between the two—instead of allowing the air, as is the usual practice here, to rush through unchecked openings injudiciously placed, causing dangerous draughts—we should have a very efficient method of ventilation.

I would next make a few remarks on their locomotives. It has been said that the difference between between English and American locomotives is in outward appearance only: this may be so to a great extent, but I think there are points of detail (and points of detail are sometimes very important) which are worthy of note and consideration. The first glance at an American locomotive gives you the impression of an old Bury engine with a bogie in front and a great deal of Birmingham finish, and one is inclined to imagine that American engineers cannot have seen English locomotives, but this idea is soon dispelled when they are examined in detail or their performances witnessed. The curves on some of their main lines are very severe: as an example, those on the Pennsylvania Central above Altoona are set out to a radius of 600 ft., not for short distances only, but in long lengths of continuous curves. The heavy traffic is worked over this section of the line by means of six-wheeled coupled engines, which in passing round the curves have comparatively no flange friction at all; the bogies of these engines have a swing motion similar to that of the carriages, which leaves the engine, to a great extent, free in front; the bogie wheels are made to correct guage, and, in order to prevent grinding or flange friction, the leading and centre driving wheels are virtually without flanges, the leading wheel having no flange and the middle wheels being very slack in guage, whilst the trailing wheels fit the gauge exactly. From this it will be apparent that there are no binding points throughout the whole wheel base. The tyres of the two middle wheels are made much broader to allow the necessary lateral travel. Four-wheeled coupled engines are also sometimes made without any flanges on the driving wheels.

The framing is made of square bar iron, well put together; plate-framing has been tried and abandoned. The slide valves are horizontal and worked by means a rocking shaft; direct-acting valves have been tried, but given up, and all engines with such valve arrangements sent from this country have been altered.

Instead of the balance weight to the link motion, a simple arrangement of coil spring has been substituted, which has a neat appearance and enables the reversing lever to work more freely.

A "Ramsbottom" arrangement of screw-reversing gear has on some lines been adopted in combination with the reversing lever, so that either one or the other can be used. The eccentric straps and sheaves are of cast iron, neither brass nor white metal being used. They wear much better, are much cheaper, and give no trouble. The smoke-box is simply a continuation of the boiler plates, and the smoke-box door is of cast-iron. This makes a strong, substantial arrangement, and at the same time cheap and easy of construction.

Steel boilers are becoming very general, and were to be found in the locomotive shops of all the railways I visited, and steel fire-boxes were also very largely employed. American engineers have no hesitation on this subject, and could they obtain good steel plates as cheaply as we can in this country, the use of iron plates would soon be abandoned. The fire-boxes are only $\frac{1}{4}$ in. thick, and some of the locomotive superintendents informed me that, were it not for the difficulty of the stays, they would have them still thinner. Thin plates are advantageous in two ways; steam is generated more rapidly and economically, and they admit of easy expansion.

Steel fire-boxes have broken in this country, but this, I believe, was owing in a great measure to the thickness of the plates. Whilst we are hesitating in this country about the use of steel boilers, the Americans have passed through the field of experiment, and are now largely using them. I saw a steel boiler tested at Pittsburg; the plates were $\frac{1}{4}$ in. thick; the boiler was 38 in. diameter and 4 ft. long, with flat ends stayed longitudinally. Some of these stays gave way with a pressure of 780 lb. on the square inch, and one end of the boiler was blown out, the thickness of the plates being much greater than in the barrel. Before bursting, the barrel stretched 4 in. in circumference beyond its original dimensions.

The weight on the driving wheels of the 4-wheeled coupled engines is from 8 to 12 tons, being very excessive for the prevailing light sections of rails.

We are astonished when accounts reach us of the number of rails broken in America, but to any one who has been over there and investigated the subject, it is a matter of surprise that the number is not greater. The weight of the rails, generally, is from 56 to 60 lb. when new, but, but after several years' hard wear this will be reduced to about from 48 to 52 lb. The rails are so crushed in many places as to reduce the section to the web and bottom only. That such rails should break with engines of 30 to 35 tons, with 12 tons on an axle, is certainly not surprising.

Though the engine plays a destructive part in the wear and tear of the rails, the wagon stock is equally, if not more, destructive. The worst feature in this department is the inefficiency of the springs under the wagons. India-rubber is employed to a great extent, and thousands of wagons are provided with nothing but small blocks of rubber of such insignificant dimensions as virtually to render the wagons without springs at all; and in winter time, especially, when the ground is frozen as hard as stone, and when the greatest amount of elasticity in the stock is required, these small blocks of rubber are practically of no value, and wagons weighing, when loaded, from 20 to 25 tons, are running dead over the frozen track. Some of the wagons, provided with steel springs, are very little better. I measured a number of the springs and found them actually not to exceed 12 in. between the bearing points, and far too stiff and rigid to afford any relief to the superincumbent load. I have seen a number of anxious American letters on the subject of rails sent out from this country, both iron and steel; but of what extraordinary material must a rail be made to stand such punishment as I have referred to, not to mention other causes which I will not now attempt to discuss.

As a brief comparison of the relative amounts of dead weight to the load carried would, perhaps, be interesting to your readers, I may mention that the American carriages generally carry about 70 passengers each. The weight of the carriages, formerly, was from 12 to 15 tons, but those recently constructed are no less than 15 to 17 tons.

The "drawing-room cars" (so called from a fear of making any avowed distinction of class, such as first, second, and third) are still heavier, while the weight of the sleeping cars are from 20 to 35 tons. The greatest difference, however, between the practice of the two countries lies in the dead weight to the paying load in their goods traffic. The largest proportion of their freight cars are covered goods wagons, measuring from 28 to 30 ft. long and about 8 ft. 6 in. wide, with a bogie at each end. The total weight of these wagons is from 9 to 11 tons, and the load they are required to carry is from 9 to 12 tons, or, practically, an equal weight of dead load to the paying weight carried.

So miscellaneous are the weights and dimensions of our English wagons that it is difficult to classify them, but taking a fair average we may safely assume that as regards dead weight we have an advantage of at least 30 per cent. in our favor.

FOUNDRY ECONOMY.

In a late lecture on "Applied Mechanics," before the Society of Arts, Mr. John Anderson, C. E., Superintendent of Machinery to the War Department, after familiarly describing the distinctive properties of cast and wrought iron and steel, proceeded to speak of the molecular structure of metals. All metals, he said, are crystalline, but the crystallization is better observed in some metals than in others. In cast iron, especially, it is very apparent. The crystallization of cast iron is governed by a natural law. This law was first pointed out, to the best of his belief, a few years since, by Mr. Mallet, and is this: When cast iron is in a liquid state—when the molecules have sufficient heat amongst them to give liquidity—the direction of crystallization is determined by the lines into space which the heat takes. When this law was first started it was received with skepticism, but ever since the law had been pointed out, he (the lecturer) had never observed in any piece of broken metal an example to the contrary. If we introduce into castings irregularity of figure, or anything which creates currents outwards in various directions, then we get wrong; we introduce lines of weakness. According to this law, guns up to this time have always been made wrong.

The Americans are acting upon this law in everything they are doing, and that gun of theirs which some time back came to this country, almost like a soda-water bottle in shape, was constructed in strict accordance with this law, and, therefore, possessed the utmost strength attainable with the same weight of metal. The molecular appearance of cast iron depends on the rate at which the heat is hastened out of the casting.

As to the goodness of cast iron, goodness for small castings is not goodness for an hydraulic cylinder; goodness for an hydraulic cylinder is not goodness for a gun. Density is a quality good for both the latter, but we don't want ductility for an hydraulic cylinder, but for a gun it is required; for the hydraulic cylinder we want very great density. As a rule, the hardness of cast iron or cast steel depends upon three things: 1, on the quantity of carbon which the mass contains; 2, on the heat to which it was raised before carrying the heat out of it; and 3, on the rate at which that heat is hastened out it. All these conditions go to determine the character which cast iron or cast steel assumes. In casting iron in moulds, where hardness is wanted, some method is adopted so as to carry the heat out rapidly, and where softness is required, means are taken to allow the heat to go out slowly, and it does not much matter what the method is so long as it is effectual. The hardness of steel depends upon the quantity of carbon which it contains, and on the rate at which the heat has been carried out of it. After alluding at some length to the founder's art, the lecturer proceeded to speak of the casting of a fly-wheel, pointing out that the only thing which would preserve such a casting intact whilst cooling was to take care that every part should cool at the same rate. The arms, being least in substance, would naturally cool first, but they must be kept hot by covering them with fire or by any other convenient means. If we require a particularly good casting, it must be cooled slowly.

Many of the difficulties of the caster would be got rid of if we could prevent the formation of the gas within the mould. The Americans are very much more careful in this respect than we are, and this is the explanation of their cast-iron guns standing so well. Mr. Babbitt uses old firebricks, which after, say ten years' service, have not changed color; any firebricks at all discolored he rejects. He grinds these to a powder, and thus gets a perfectly pure and refractory material for his molds, using pipeclay, the best material for the purpose, to render it adhesive. The mold is first made red-hot, and this red-hot mold then receives the metal. Not a particle of gas is generated by the mold. Another American founder, Mr. Hains, uses kaolin, which he obtains from England (Devonshire), and treats it in a similar way to that in which Mr. Babbitt treats his powdered firebricks and pipeclay. To show the earnestness of our American competitors—and we shall have them as competitors—they resort to the method of of taking the heat out of the castings in the way which would be least injurious to them. They try to establish the conditions of a built-up gun in a cast-iron one, to have every atom of the gun under tension. We English, as a people, must pay the same attention to natural laws as the Americans and the French are doing.

ELECTRICITY AS A MOTIVE POWER.

From the "American Journal of Mining."

Some time ago we touched lightly on this subject in an article entitled: "Electricity and Steam." We pointed out how much more expensive the former is than the latter, for the simple reason that the source of the first power is zinc, a product of art, and of the latter coal, a product of nature, also that if we add to the difference in price, the difference in the chemical equivalent which makes six pounds of coal as effective as 64 pounds of zinc, we obtain as a result that zinc will be more than 100 times more expensive than coal. But the difference in coal is practically even more than this. For the oxidation of the zinc acids are needed, also products of art, and for the oxidation of the coal or carbon common air, a product of nature, literally costing nothing at all. Now, as there is no reason whatever to suppose that electric engines are more perfect than our best steam engines, with all the modern improvements, for the reason that our experience in manufacturing electric engines is very small, and in the steam engines very great, we may confidently assert that the continual running of an electric engine for practical purposes would at the present day cost a thousand times more than the amount incurred by a steam engine, so that the amount of power obtained from the first, at a cost of ten dollars, would be obtained from the last at a cost of only one cent.

Notwithstanding this, we see from time to time inventors—who, by the way, are often apt to forget what should be the final question in regard to all enterprises ; will it pay?—basing their experiments upon our present highly expensive sources of electricity, and contriving new combinations of currents and magnets, hoping by some scientific hocus-pocus combination to obtain a miraculous effect. Some twenty years ago there was a large electric engine mania among inventors, just as there is at the present day in regard to ice and cooling machines. Scarcely a month or even a week passed that some new combination of electro-magnets of peculiar form, was not exhibited, usually patented, as each inventor supposed his combination to possess such superior advantages to outdo all competitors in that line ; often, however, the peculiarity insisted upon by the inventor, as a great advantage, turned out to be a defect, and the machine would perhaps scarcely go at all. We remember in this connection some machines remarkable for the total want of theoretical knowledge shown by the inventors. One of them had enormously elongated pole ends at the electro-magnets, the inventor erroneously supposing that their large surfaces of iron would exert great attraction, and not knowing that such elongated poles acted like attached keepers, absorbing almost all the attractive power developed by the coils; however, the machine was made on a large scale, at the expense of several thousand dollars, and when finished, showed much less power than the simple machine—in fact, it scarcely moved at all.

In order that the uninitiated reader may fully understand all this, and what is to follow, it is only necessary to state, that when a piece of soft iron is surrounded by a coil of insulated copper wire, and an electric current passed through this wire, the iron will become a strong magnet, and lose its magnetism at once when the current is interrupted. All that is necessary, therefore, to cause intermittent attractions is an intermittent contact with the electric battery, and these attractions will cause to-and-fro motions, which by means of a crank may be changed into rotary motion ; or the intermittent magnets may be placed on the circumference of a wheel, and attract similar other magnets, or as many pieces of iron ; the contacts with the battery being made and broken, by means of some automatic arrangment worked by the motion of the machine itself.

Numbers of such contrivances have been made, and may be seen in every physical cabinet; but in fact they are in a physical point of view mere illustrations, of the properties of electro-magnets. When considered in a mechanical point of view, they are mere toys; and in reality there never was a machine of this kind yet constructed, even on a large scale, which was in reality more than a toy.

But not only these so-called electro-magnets will attract one another, or attract iron, but the currents themselves will attract each other when running in the same direction, and repel one another when running in opposite directions.

This was discovered by Ampere in France, some 40 years ago, and has given rise to a new branch of physics, called electro-dynamics. It was first applied to moving machines by Mr. Vergnes, from France, living in New York City, who had made the study of electricity a speciality, and, in the ambition of his inventive genius, again overlooking the great ultimate question as to cost, constructed the largest electric motive engine perhaps ever made. It was repeatedly on exhibition, and was shown in the Crystal Palace, New York, at the world's fair in 1852. It worked admirably, and with seemingly considerable power, which, however, never was measured. It is a curious fact that in any machine of this kind the inventors always oppose most strenuously any such measurement. The battery used was enormous, many hundreds of cups and carboys of acids being in operation, so that the expense must have been ruinous.

In this machine Mr. Vergnes had wisely combined the attraction of the iron of the electro-magnets, with the attraction and repulsion of the currents themselves, according to Ampere's discovery; for the reason that the attraction of the currents, or rather of the wires conducting the currents, is comparatively very weak, so that quite a strong battery is required to demonstrate this attraction at all, while the attraction of electro-magnets will manifest itself most strikingly with a battery of one-hundredth part of the size of that required to cause the mere currents to attract each other. This fact is well known to every one who has ever experimented with voltaic batteries, currents, etc.

Taking all this into consideration, we cannot disguise our great surprise, that the newspapers should this week contain a glowing description of a so-called newly-invented electro-motive engine of M. Griel, a French military officer, based on the action of currents on currents; asserting that all inventors thus far had confined themselves to the use of electro-magnets, and that here for the first time the laws of dynamical electricity have been brought into play.

Now the fact is, that if not in all, at least in most philosophical collections, there are pieces of apparatus, in which, on a small scale, this principle is illustrated, and Vergnes, mentioned before, has, with many others, put this principle in practice, but found that when discarding the use of electro-magnets entirely, the most advantageous effects were lost. No doubt Mr. Griel's machine would be stronger if advantage were taken of the powerful magnetic action acquired by soft iron under the influence of electric currents, in place of confining the power to the comparatively weak attraction and repulsion produced on the pure electro-dynamic principle.

The battery described for driving this machine is identical with Bunsen's, namely amalgamated zinc, diluted sulphuric acid, porous cups, strong nitric acid and coke. It appears to be of enormous dimensions, and of course correspondingly enormous expense.

The most curious thing, however, is the calculation of Mr. Griel, by which he attempts to prove that when using steam the expense increases in direct ratio of the horse-power obtained, and that when using his machine, it will only increase somewhat as the cube-root of the power obtained, as shown in the following table given by him:

Horse-power obtained.	Expense— Steam.	Electricity.
2	..	..
16	$8	$2
64	16	3
250	125	5
2,000	1,000	10

and conceding that for two horse power electricity costs 25 times more than steam, when using 250 horse power it becomes equal, and for 2,000 horse power it will be four times as cheap.

Now, the fact is that electricity, in the way he obtains it, is not only 25 times, but 1,000 times more expensive than steam, and that the calculation of relative reduction of expense for greater power is entirely false and erroneous.

To crown all, he states that he can apply his machine to railroads, and by means of an electro-magnet of his invention (most wonderful) cause the electricity to wash from the wheels of the machine upon the rails, and proposes to ascend any grade with the greatest facility.

It is now several years since M. Nickles, of France, who, we regret to say is recently deceased, proposed to accomplish the same thing by similar means, and about six years ago the same idea was again revived by an American inventor, who tried to prevent the slipping of the driving wheels on the rails by exactly this plan, making that part of the wheel which touched the rail a temporary electro-magnet. It was tried, at great and prolonged labor and expense, but given up as totally impracticable. One French inventor goes even further, and appears to have the intention of also driving the cars forward by his machine.

It is matter for surprise, that the editors and reporters of our public press, otherwise so well informed in matters political, religious and otherwise, are so little posted on scientific matters, as continually to be deceived by the pretentious claims of inventors. True men of science too often meet with cold contempt, while charlatans and deluded enthusiasts are received with almost superstitious credulity.

TORPEDOES.

From the "Pall Mall Gazette."

The strides which have been made within the last ten or fifteen years in the application of science to warlike purposes are nowhere more marked than in the use of electricity as a military agent. It is applied to military telegraphy, to signalling and reconnoitering purposes, to the determination of the ballastic powers of guns, to many naval uses, such as signalling and the simultaneous discharge of broadsides; to various experimental purposes, including the proof of guns; last, but not least, to the explosion of land and submarine mines. The history of the subject and its most recent phases were treated a few nights ago at the Royal Institution by the gentleman to whom above all others we are indebted for the development of this special branch of application of the science. The interest of Professor Abel's excellent lecture centered, however, in his account of what has been done in this country towards the establishment of a system of torpedo defence. It was the first authoritative utterance on the subject which has yet been heard, and the immense importance of the question, combined with the secrecy in which it has thus far been shrouded, suggest the desirability of taking advantage of the occasion to say a few words about it.

Torpedoes form the most important class of those marine obstructions which are now generally admitted to be indispensable to effective coast and river defense. They are the active as contradistinguished from the passive obstructions. The importance of obstructing roadsteads, rivers, and harbors —of placing, so to speak, an outer belt or circle of defenses, external to the chain of forts, and even where no forts existed—has long been understood. It would be difficult to assign a date to the first employment of rude appliances of some sort for effecting this object; even submarine mines, which are a more advanced type of defense than piles and artificial barriers and fire ships, were used as far back as the sixteenth century, when they were employed, in 1583, by the Duke of Parma at the siege of Antwerp. The English used them against the French ships off Rochelle in 1628, and during the long lapse of years between 1628 and 1854, the subject was never wholly lost sight of. Always there were men with contrivances more or less ingenious, more or less impracticable, ready when the opportunity offered to revolutionize with their torpedoes the art of coast defense. But science was during that time in its infancy. The torpedoes in occasional use prior to 1854 were rude and imperfect, and the development of the subject was cramped by the absence of sufficient knowledge or study to enable electricity to be usefully employed as the agent of ignition. Thus the first torpedoes were of the mechanically exploding class. All sorts of plans were devised and all sorts of agents were employed—percussive, frictional, chemical, and clockwork. It is evident, however, that mechanical torpedoes can never be altogether satisfactory. They are open to one salient objection, viz, that once in position and ready for action they close the navigation alike to friend and foe, and there is always a certain amount of danger attending their manipulation. These evils have been attempted to be mitigated by various safety arrangements, so-called, the application or the removal of which, however, as often as not proves so dangerous as to furnish a formidable objection to their employment. Thus, when the Russians employed, for the defense of Cronstadt, mechanical torpedoes with a safety arrangement, which should have been removed at the last moment, they generally, for very good reasons of their own, neglected to remove it, and the torpedoes in consequence proved absolutely innocuous. Again, the removal of the torpedo is frequently a source of danger, and several instances have recently occurred in America of loss of life under these circumstances. Nevertheless, mechanical torpedoes will probably always possess a certain value, as on remote foreign stations, where the means of defense have to be extemporized on an emergency, or for what are called "drifting" or movable torpedoes. This abortive employment of torpedoes in the Russian war of 1854–5 marks the first systematic use of the instrument in European warfare on a large scale. In 1855 electrical torpedoes were attempted; and by 1859 the Austrian Government had succeeded, with the assistance of Baron von Ebner, in perfecting a sufficiently simple and practical system of electrical torpedo defense, which was applied, although without results, at Venice. Until lately the Austrians may be said to have headed the science, and their exhibition of a complete system of torpedo defense formed an interesting part of the display at Paris in 1867. No really important illustration of the great value of torpedoes was furnished until the late American war, when these agents were employed in many forms, chiefly by the Confederates, and with remarkable results. No less than twenty-five vessels of the Federal navy were destroyed and nine others were injured by the explosion of torpedoes; and thus an impetus was given to the subject, similar to that which breech-loading derived from the Bohemian campaign of 1866. If any one wishes to study the detailed application of torpedoes during the American war, he can hardly do better than consult Von Scheliha's *Treatise on Coast Defense*, where also he will find the following important deductions from the experience obtained during this contest: "No forts now built can keep out a large fleet unless the channel is obstructed." "No fleet can force a passage if kept under fire by obstructions." "*In no single instance did a naval attack succeed when the channel had been obstructed, and in no single instance did it fail when the channel had remained open.*"

The attention of our Government was directed to the subject towards the close of 1863, when a committee was appointed, at the suggestion of Colonel Jervois, R.E., for the thorough practical investigation of the whole question of marine obstructive defense. From that time until the latter part of last year, the committee was actively engaged in an experimental inquiry, and the result has been the compilation of a report which is likely to prove the most complete and exhaustive treatise on the subject yet produced. Hitherto the report has been treated as confidential, and it is, no doubt, desirable that the details of the committee's recommendations should remain secret. But no objection can be urged against the production of so much of the report as would inform the public in general terms of the successful termination of the committee's labors, and of the broad results purchased at a not inconsiderable expenditure of time and money. It would be satisfactory to have some definite and authoritative assurance that the national interests have not been neglected in this vital question of defense, as well as an assurance that the recommendations of the committee will be duly and practically accepted. We observe that the very inadequate sum of £2,000 has been taken in this year's estimates for the provision of torpedo equipments, and for further inquiry and instruction. The gunnery ships of Portsmouth and Plymouth, and the Engineer's School at Chatham, now regularly include the use and management of torpedoes in their course of instruction.

To return to the torpedoes themselves. We have stated that mechanical torpedoes, however occasionally useful, are necessarily imperfect and, to a great extent, dangerous appliances. The advantages which attach to the application of electricity to the explosion of torpedoes are great and manifest. Torpedoes of this class may be placed in position with absolute safety to the operators; they may be rendered active or passive at any moment, as desired; they thus do not close to friendly vessels the channels which they guard; they can be stationed at any depth beneath the surface; their action is generally very much more certain than that of a mechanical torpedo; and they can be removed with perfect safety. As in the case of torpedoes of the mechanical class, the arrangements for securing action may be almost infinitely varied. Frictional, voltaic, dynamo-electric or magnetic electricity may be employed, each possessing specific advantages or objections; and the circuit which determines the explosion may either be completed by the contact of a passing vessel or at the right moment by an operator on shore. The latter system, which admits of many modifications, is probably the more simple; but it imposes the necessity for great vigilance, promptness, experience and harmonious co-operation on the part of the operators. It is also inapplicable at night or in thick weather, and might even fail under the dense smoke of a hot action. A more generally efficient plan is that of contact-exploding torpedoes, which are either exploded by their collision with a ship, or by the vessel striking a circuit-closing arrangement moored near the surface of the water, whereupon either the torpedo, moored at some depth beneath, is instantly exploded, or a signal is furnished to a station on shore, which indicates to an operator the particular torpedo to be fired, and when to fire it. It is essential in this arrangement to adopt a plan which, while sensitive to the passage of a vessel, shall not be disturbed by the simple action of the waves. These conditions include the necessity for simplicity of mechanism and a combination of sufficient but not excessive delicacy of action, with permanence during long immersion; but the problem, though difficult, is not insoluble, and one or two plans have been suggested which appear to satisfy the required ends. It seems to have been established that voltaic electricity is, of all the means available for the purpose, the one which presents the greatest advantages. And the substitution for the old platinum wire fuze, of the Abel fuze, in which the electric spark is generated by the interrupted passage of the current through a priming material of subsulphide of copper, subphosphide of copper, and chlorate of potassa, permits of the use of electric batteries which were before inapplicable, and of the explosion of torpedoes with perfect certainty at distances before unattainable. Indeed, the introduction of this fuze has rendered possible the development of torpedo science which has now been attained. The batteries may be of the simplest character, and a very efficient one can be readily extemporized with a piece of hard timber, a little zinc and copper sheet, an old blanket, some vinegar and common salt. A battery of this sort, weighing only 25 lbs. and about $7\frac{1}{2}$ in. square, will remain in good action for at least twenty-four hours, and can be easily cleaned and recharged. Such a battery, from its small size, weight, and great simplicity, is especially well adapted for boat operations.

The explosive agent to be employed in

torpedoes may be gunpowder, nitro-glycerine, or gun-cotton. Of these, gun-cotton is on many accounts preferred; and since the recent discoveries as to the susceptibility of gun-cotton to explosion by concussive effect, and the great resulting increase of power, its normal advantages have become more decided. There still remain a vast number of points, such as the nature of case or envelope to be employed; its thickness; the depth to which the torpedo should be sunk; the positions in which it should be fixed; the proximity of one torpedo to another; the the size, form, &c. The bare enumeration of these points will suffice to indicate that the subject is one which admits of an immense deal of working out, and will, perhaps, account for the length of time occupied in its investigation.

As to the practical value of torpedoes we have furnished some illustrations. But, in truth, it is unnecessary to multiply illustrations, for the value of these instruments may almost be regarded as self-evident. There are two points in every ship absolutely unprotected—the deck and the bottom. Of these the torpedo attacks one—the bottom. And it is a question if any ship can ever be made so strong as to resist the effect of a powerful submarine mine exploding directly under it. The use of torpedoes is not limited to serving as auxiliaries to forts, or as a means of keeping vessels under the fire of batteries. They are useful also on their own account, as a means of defending positions independently on a coast or in small channels and rivers which are quite unprovided with defensive works. Their invisibility forms another element of their importance, to which we may add their comparatively small cost and ready applicability to almost all positions. But it is necessary to guard against the impression that torpedoes are destined to supersede other and more old established means of defense, as ships and forts and guns. Invaluable as auxiliaries, and even as independent means of defense, their value is limited by two considerations. In the first place, the sphere of action of a torpedo is small; as compared with that of a fort or ship, exceedingly small; and an attacking vessel is safe as long as it contrives or chances to keep outside that area of destructive effect. In the second place, no torpedo can act more than once, and when it has exploded, the area of water which it guarded becomes defenseless. But with these limitations, their value can hardly be over-estimated; and it is satisfactory to know that the subject has been thoroughly and practically considered, and that we possess on paper at any rate a scheme for their use so complete as to relieve us from all anxiety on this score. It would, however, be more satisfactory still to know something definite as to the recommendations of the committee, and we hope that some member will think proper to ask in the House for such portions of the report as can be discreetly made public.

THE STABILITY OF FLOATING DOCKS.

From a paper on the Iron Floating Dock of Carthagena, its proportions and relative stability, read by George B. Rennie, M.I.C.E., before the Institution of Naval Architects.

The form of this dock may be briefly described as an oblong rectangular box or trough, without a top or ends, the walls and bottoms of which are hollow, and divided into several independent chambers. The vessel to be docked is placed between the side walls, and is raised completely out of the water by the buoyancy of the bottom of the dock. The side walls act as floats to prevent the dock sinking too rapidly, and eventually from being entirely submerged.

The operation is performed in this way, water is allowed to flow into the different compartments forming the base, by means of sluices, and distributing pipes; the dock then gradually sinks, until the buoyancy of the chambers, forming the side walls, becomes equal to the weight of the entire structure; that is, when it is desired to sink the dock to its greatest depth for the purpose of taking in the deepest draught ship the dock is intended for, for vessels of less draught it is only allowed to sink to a depth sufficient for the particular vessel. The vessel is then hauled in between the walls, and the engines and pumps of the dock set to work to discharge the water from the bottom or base; when empty, it is capable of sustaining a weight of ship (less the weight of the dock), equal to the total displacement of the bottom or base. The vessel is shored up in the usual manner adopted in the ordinary graving dock.

The dock is entirely of iron, with the exception of the decks, shoring steps or altars and fenders, which are of timber. It is strengthened both longitudinally and transversely by bulkheads, which form the divisions of the chambers, as well as by intermediate lattice framing, which give the structure great stiffness.

The dock for Carthagena was commenced in 1859, sent out in pieces from England, and erected at Carthagena in a shallow basin prepared for the purpose, and when completed water was let into the basin and the dock floated out. When first floated, it was found to have an uniform draught of water of 4 ft. 7 in.; this gives a total displacement of 4,400 tons of sea water, which is equal to the weight of the dock complete.

Some of the largest vessels which it has raised are the frigate Princessa de Asturias, of 3,810 tons, and 21 ft. draught of water, the frigate Villa de Madrid, of 27 ft. 6 in. draught, weight unknown, the ironclad Sarragoza, of 4,972 tons, and 25 feet draught, and the ironclad ship Numancia, of 5,600 tons weight, and 24 ft. 1 inch draught, this latter vessel remained supported for eighty days, without causing any damage to or undue straining of the dock. The weight of this ship was further tested by the depth of flotation of the dock as observed with the ship on it; this was ascertained to be 11 ft. 3 in., giving a total displacement of 10,800 tons of sea water; but on examination of the different chambers it was found that there was about $7\frac{1}{2}$ in. depth of water in the lower ones and $7\frac{1}{4}$ in. in the middle ones, equivalent to 800 tons weight; this added to the weight of the docks, 4,400 tons, gives 5,200 tons, leaving 5,600 tons as the weight of the ship. The dimensions of the Numancia, the largest of the above named vessels, are as follows: length (perpendicular), 316 ft.; extreme breadth, 57 ft.; displacement at load draught, 7,420 tons.

The dimensions of the dock are as follows; length, 320 ft.; breadth outside, 105 ft.; ditto inside, 79 ft.; height outside, 48 ft.; ditto inside, 36 ft. 6 in.

If the few inches of water remaining in the base and middle chambers were entirely removed, the draught of water of the Carthagena Dock, with such a vessel as the Numancia, of 5,600 tons weight, would be 10 ft. 6 in.

The main proportions of the dock are as follows; the length is between 3 and $3\frac{1}{4}$ times the breadth. The width between the walls at the top is $\frac{3}{4}$ of the breadth. The floor of the dock is $\frac{1}{2}$ the breadth. The height of the side walls is somewhat under $\frac{1}{2}$ the breadth. The depth of immersion 1-10th of the breadth. These proportions are suitable for almost all sizes of floating docks of the rectangular form. Thus, supposing a dock to be made capable of lifting and sustaining a vessel like the Achilles, of say 10,000 tons weight, the breadth would be 120 ft., the length 400 ft., the width inside 90 ft., the "floor" 60 ft. in width, and the immersion 12 ft.; total displacement 16,457 tons.

In calculating the height of the metacenter, or the greatest height the weights may be raised above the center of displacement of the immersed body at an angle of inclination, say of 10 deg.; and taking the distance between the centers of gravity of the immersed and emersed portions due to the inclination at two-thirds the total breadth, and multiplying by the portion immersed, and dividing by the total volume immersed into the sine of the angle of inclination, it will give 90.75 ft. for the distance of metacenter from the center of gravity of the volume immersed, or 85.5 ft. above the line of flotation for the Carthagena dock, whereas the center of gravity of the entire structure and ship is calculated to be only 18 ft. above the line of flotation, allowing for a ship of 26 ft. 6 in. draught of water on keel blocks 4 feet in height.

In the dock proposed, the metacenter, is 101.5 ft. above the center of gravity of displacement, or 95.5 ft. above the line of flotation, and the centre of gravity of the dock with the Achilles, is calculated to be only 19 ft. 3 in. above the line of flotation.

In calculating the amount of statical stability of the dock at Carthagena with an immersion due to the weight of such a vessel as the Numancia, of 5,600 tons, it is found that supposing the inclination to be 10 deg., that the moment of stability will be 360 when reduced to feet and tons per foot in length of the dock, or a total of 118,080 tons for 320 ft.; and the dock proposed would have a moment of stability of 549.2 when reduced to feet and tons per foot in length, or a total of 219,680 tons for 400 ft. This is nearly as the cube of the breadth, and directly as the length.

Comparing this latter with a dock of a U-shaped section, with water ballast, like that actually made for Bermuda, as calculated from a lithographic drawing, giving the particulars of this dock, it is found that the moment of stability equals 660 foot-tons per foot in length, or for the length of 333 ft., a total of 219,780 ft.-tons, or about the same as the one proposed, of a rectangular form.

A further comparison of the dimensions, weight of ship to be docked, height of metacenter of these two forms of docks, may not be without interest:

	U-shaped Section.	Rectangular Section.
Available length of dock for the largest ship....	333 ft.	400 ft.
Extreme outside breadth..	123 ft. 9 in.	120 ft.
Extreme inside breadth...	85 ft.	90 ft.
Breadth of "floor".......	50 ft.	60 ft.
Draught of water with heaviest ship.	40 ft.	12 ft.
Area of immersed section ditto................	4,000 sq. ft.	1,440 tons.
Greatest weight of ship capable of being docked	8,000 tons.	10,000 tons.
Weight of dock..........	8,350 tons.	6,475 tons.
Center of displacement below line of flotation.	18 ft.	6 ft.
Distance of metacenter from center of displacement............	38 ft. 6 in.	101 ft. 6 in.
Distance of center of gravity from center of displacement.........	5 ft.	25.3 ft.
Centre of gravity above or below line of flotation.	13 ft. 3 in. below.	19 ft. above.
Moment of stability per foot in length of dock..	660 tons.	549.2 tons.
Total for whole length of dock................	219,780 tons.	219,680 tons.
Draught of water to take in a ship of 26 feet draught with keel blocks 4 feet in length.......	50 ft.	45 ft.

From the above comparison, it will be seen that a dock of rectangular form of the same proportion as that of Carthagena, will have the same total stability as the U form of dock, require about one-fifth less material for its construction, and be capable of supporting a longer ship of one-quarter greater weight, and with less draught of water. Moreover, the arrangements for docking are less complicated; for when the ship is once on the keel blocks, pumping is the only operation to be performed, as there are neither gates nor caissons to close in the ends.

To represent the relative stability of different forms of section in a clear and simple manner (although not so accurately as may be found geometrically or mathematically), the following table is compiled from experiments on different sections made of thin copper, to a scale of 10 ft. to the inch. The models were all 9 in. long; the leverage was taken at 8 in. from the central line of the model.

The lead weights representing the ship were cylindrical, and supported on their axis, at a distance representing the height of the center of gravity of the ship, above the floor of the dock of 27 ft. 6 in.

In the table, A and B represent sections of docks, of the form proposed and that actually executed. It will be seen on comparing the inclination of these two forms with the same weight and leverage, that B, the U shape, gives greater stability per unit of length than A the ⊔ shape, but as the model U was made by mistake to represent 127 ft. 6 in. in breadth instead of 123 ft. 9 in., the relative stability as shown by the angle of inclination is somewhat greater than calculation indicates.

The model C shows how the stability of the same form of section may be increased, by the addition of water ballast at the bottom.

The model D, segmental form, may, with the addition of water ballast, have nearly a stability equivalent to the form A.

The model E represents the Carthagena dock, with its angles of inclination, and with the same weight and leverage as the other models.

Although it may be seen from this that other forms may have a stability equivalent to that of the rectangular or flat form, it can only be done by the addition of a considerable amount of water ballast, which so increases the draught of the dock as to necessitate the ends being closed in.

The Carthagena dock, as before mentioned, was sent out from this country in pieces, and erected in a shallow basin made for that purpose, at Carthagena; this on the whole (when practicable) seems the most safe and simple plan, and the basin is moreover available when required for taking in the floating dock for the purpose of cleaning, painting, or repairing.

Wooden floating docks of somewhat similar section to that of Carthagena have been towed to their place of destination, as was the Pola dock, from Venice, the Havanna dock, from New Orleans, and more recently, that of Alexandria, from the south of France, but the square ends of this form are no doubt ill adapted for being towed through the water.

In order to meet this difficulty, when it was contemplated to tow a dock across the Atlantic, a modified arrangement of the rectangular form was proposed by Messrs. Rennie, better adapted for being towed through the water. The side walls were to be reduced to about two-thirds of the length of the floor of the dock, the rectangular ends of the floor to have been rounded off so as to form pointed ends, upon which temporary sides were to be raised to the required height, in order that the dock might be decked over from end to end; this deck, together with the temporary sides, would have to be removed on arrival at its destination.

Considering the length of the voyage, it was thought that the empty space below the deck might be available for the stowage of coals and other stores to supply (during the voyage, the steamers employed to tow the dock out. This form of dock would not have required a basin as at Carthagena, and the necessary repairs could have been effected by means of a rectangular iron box lowered under the dock, and placed against the defective part, and the water pumped out from within it. The joints between the box and the bottom of the dock being previously made water-tight by means of an elastic substance, or the water kept out by a pressure of air, which, in this case, would not have exceeded 3 lb. per square inch.

In conclusion, it is considered that floating docks of the form and proportions to that of Carthagena will have ample stability for the heaviest ship to be docked.

That it is of the simplest construction.

That the smallest amount of material for a given strength and stiffness will be used in its construction.

That the cost will be less than for other forms of section.

That the simplest docking arrangements and safety of the dock are best attained by that form.

And lastly, that by the modification suggested in the paper, they may be towed with comparative safety to any part of the world.

A Table of Experiments on the Stability of different Sections of floating Docks, made on Copper Models. Scale of 10 ft. = 1 in.

Form of Section.	Weight of model in ounces.	Weight representing ship in ounces.	Approximate proportion of dock to ship.	Breadth of model to scale in feet.	Height of center of gravity of ship from floor to scale in feet.	Degree of inclination with weights, at a leverage of 8 in.

THE CENTRAL RAIL SYSTEM.

ABSTRACT OF REMARKS BEFORE THE SOCIETY OF FRENCH CIVIL ENGINEERS.

From the "Compte Rendu des Séances." Translated from "Annales du Génie Civil."

For some years the development of railways has gradually given rise to a new problem for engineers, viz: the construction of engines capable of overcoming heavy grades without involving any considerable change in the present systems of *exploitation.* At first, inclined planes were used, up which the trains were drawn by cables; then the Engerth engines, and engines constructed for the Northern railway, &c.; latterly, the funicular system of M. Agudio, and finally, the Fell engine, working upon a central rail, as proposed by Baron Seguier. A similar engine was discussed by M. de Landsèe, before the Society of Civil Engineers at their last session in November. He remarked that the experiment of crossing Mont Cenis had been favorable to the central rail, which permitted the ascent of grades hitherto unused in railways. The engines, through the supplementary adhesion obtained by means of a group of horizontal wheels upon a median rail, have a tractive force equal to at least twice the weight of the engine. He has laid down the principle, in the plan which he has developed, that the engine for the central rail should be able to operate upon an ordinary road at certain points. This condition seemed necessary to him in order that its work may be done easily and conveniently. He accordingly supposes the median rail to be absent at switches, on bridges and at all parts of the road where the grade is easy enough to dispense with it. The locomotives should be adapted to ascend grades of 70 millimeters per meter (369.6 feet per mile), with curves of 50 to 60 meters radius. The type of engine which seemed to him best suited to the case was that having four coupled wheels. The proposed engine weighs 25,000 kilog. without load, and 26,000 kilog. loaded (28 or 30 tons), each axle sustaining 13,400 kilog—a moderate load for steel rails. According to the tables of M. Vuillemin, this engine, on a horizontal track, could draw 400 tons, but in a mountainous country such a load would be excessive, the maximum being 130 tons, and M. de Landsèe has calculated that for trains of 125 and 85 tons, this engine can ascend grades with the following velocities, &c.:

Velocity in kilomet. per hour.	Velocity in miles per hour.	Supplementary adhesion in tons.	Train 125 tons grade.		Train 85 tons grade.	
			Millim.	Feet pr mile.	Millim.	Feet pr mile.
20	12.4	0.	16.8	88.7	24.3	128.3
14	9.	28.8	41.3	218.	58.2	307.3
10	6.2	30.	50.	264.	70.	369.6

M. de Landsèe shows, that for engines weighing 20 tons loaded, and 17.5 tons light, on a road 1.10 m. guage, a median rail will be necessary for a train of 60 tons when the grade exceeds 137.3 feet per mile; with a supplementary adhesion equal to the weight of the engine, grades of 322 ft. per mile are admissible; and reducing speed to 6.2 miles per hour, the inclination, with a maximum adhesion, may be 369.6 ft. per mile. With engines weighing but 10 tons, under the foregoing conditions, the weight of the train may still be 30 tons on a grade of 369.6 ft. per mile. Since it results, from the experiments of M. Forquenot, that the evaporating power of engines depends upon the rapidity of exhausts, and therefore upon the speed of the train, M. de Landsèe suggests the use of four cylinders, two to drive the vertical, and two the horizontal wheels; thus attaining 8.884 exhausts per second for an engine moving 12.4 miles per hour, with with wheels of .80 m. (2 ft. 8 in). In such a case, the boiler, in the ascent of a grade of 369.6 ft. per mile, will have but 87 sq. meters of heating surface at a pressure of 10 kilog. per sq. cent, with a back pressure of 1.50 kilog. per sq. cent. The two pairs of cylinders being independent of each other, the engine can be run without using the horizontal wheels. The coupling of the exterior and interior wheels is effected by the steam; for this purpose the movement of the valves is taken from the rear wheel and transmitted to the valves by means of two distinct levers. A relieving axle is common to the two pairs of cylinders. The admission of steam to each pair is controlled by a special regulator, allowing the starting or stopping of the horizontal wheels while the vertical ones are in full motion. The grip of the horizontal wheels is given by means of a lever at the command of the engineer, and a guage is provided which shows the amount of grip. The coupling is effected by means of two small bevel gears. The real object of the coupling is not so much to transmit a great effort, as to ensure uniform motion and the passing of centers—each pair of wheels being controlled by one cylinder. Owing to the practicability of dispensing with the supplementary adhesion, this engine may be classified with other types in use, and can travel on any road in actual operation.

In answer to some remarks on the subject, M. de Landsèe observed, that a single distribution was employed merely for the purpose of simplifying the mechanism, but that nothing would prevent the use of separate distributions for each pair of cylinders.

PASSENGER STEAMSHIPS.

From "Engineering."

The gradual growth of science and experience has been attended with the most striking changes in the material, size, form, structure, machinery and working results of ocean passenger steamships. Where we had timber-built ships, all, or nearly all, are now built of iron; where the tonnage was once 1,000 tons, or so, it is now three times as much, or even more. Where the lines were once full, and the beam wide in proportion to the length, we now see sharp, fine, fore-and-aft bodies, and lengths of from eight to ten, and even eleven times the beam. The hulls, even when referring to iron ships only, have been greatly changed in structure; where only paddle engines were employed, screw engines are now almost universal; and where we once had but ten knots, we now have fourteen, with the same, if not an even less, consumption of fuel, although the difference in propelling work done represents a difference even greater than that between the cubes of these speeds, or that between 1,000 and 2,744.

It may be questioned whether naval art has not advanced more rapidly than any other branch of structural and mechanical science, and even admitting that it has, there still appears to be a wide field for its further progress. There are many reasons why passenger steamships should undergo further changes as radical as those so well known to be going on in the navy, and it may happen, and that at no distant time, that masts, spars and sails will be dispensed with altogether, as indeed, for very fast steaming, they must be, inasmuch as, at high speeds, the point is soon reached where sails, instead of aiding, only retard the progress of a ship.

Apart from questions of masting and rigging, it is possible also that a great change may take place in the size and form of passenger steamships. For the same displacement longer, wider and shallower ships seem desirable. It is not depth, or great draught of water, that is wanted in passenger vessels, but deck room, and, generally, open-space and light. These are the great requisites for ocean passenger traffic. For convenience of comparison merely, we may suppose two vessels of rectangular form; in other words, they shall be rectangular boxes. Each shall have a length equal to eight times the beam. Let one be 320 ft. long, 40 ft. beam, and draw 20 ft. of water, thus displacing 7,314 tons, and presenting 27,200 square feet of bottom, side and end surface, or skin, under water. The area of immersed midship section would be 800 square feet.

Another ship, having the same displacement, might be made 403 ft. long, 50.4 ft. wide, and 12.6 ft. deep. Its "skin," or under water surface, would be 31,752 sq. ft. in extent, but its midship section would be only 635 square feet in extent. Its deck area would be 20,320 square feet, or nearly half an acre, as against 12,800 square feet on the other and deeper vessel. This comparison refers, for convenience only, to rectangular boxes, but in both cases the vessels are eight beams in length, and the same proportions of deck area, frictional surface, and midship section would hold good when these boxes were hewed to the forms of fast steaming ocean ships. In plan, the lines, excepting only in scale, would be identical in both, the difference being only in the transverse section. The longer and wider ship would have a greater superficial extent of hull and deck, and, consequently, a heavier hull, but, possibly, she might have one deck less than the shorter, narrower and deeper ship. The longer ship would also, perhaps, require additional stiffening to compensate for her shallowness, not so much with reference to her riding the waves, but for her strength in the event of taking the ground or going upon a rock. She would, in any case, be much the roomer and easier passenger ship, and it is a question whether she would not require less power to drive her. The elements of this question appear to be well within grasp.

It has been the fashion among many naval architects of late years to attribute the greater portion of the resistances to vessels driven through the water to skin friction. Yet our two imaginary rectangular boxes, moving at 14 knots an hour, or 23.6 ft. per second (and as for this matter they need only have a rectangular midship section), displace respectively 540 tons and 428 tons of water per second. This water must absolutely be moved out of the way, and the power expended in putting it into motion varies according to the form of the ship, with the fineness of the lines at and below the water level. All ships must displace their own weight of water in running from about one-half to three-quarters of their own length, according to the fineness of their lines. If the average velocity given to the water be computed, as it may be, with some pains, at each successive depth of, say, a foot of draught, the power expended on this work alone may be readily calculated, and it will in all cases be found to form a very large, or let us say the larger, portion of the total power actually and effectively exerted in propulsion, this power being, on the average, but about two-thirds of the indicated power of the engines. It is, of course, supposed that the ship is all the time in hydrostatic equilibrium at both ends, the water running in at the stern and under the quarters exactly as fast as it displaced at the bows—and the mistake must not be made of supposing that the influent water compensates, in the least degree, for the loss of power in forcing aside the water in front. In this comparison, the longer, wider, and shallower ship, having but 635 square feet of midship section, would have the advantage over the shorter, narrower, and deeper ship of 800 square feet of midship section, the difference being in the exact ratio of the midship sections themselves. On the other hand, however, the longer ship would have a wetted surface almost exactly one-sixth greater than the shorter ship. Hydraulic friction is independent of pressure or head of water, being the same per square foot at the same velocity at all depths. Colonel Beaufoy found the skin friction of each square foot of painted wood to be 1.3 lb. at 13 knots an hour, and, according to his experiments (although they were made some seventy years ago, and possibly under circumstances of error of observation), he found the friction to increase in a proportion less than as the squares of the velocities. Applied to the case of steam vessels, it is demonstrable that skin friction, except in very long, very fine, and very shallow vessels does not form the principal resistance to motion. And in the cases of the two vessels already supposed, the somewhat greater skin friction of the longer ship would be much more than compensated by its lesser midship section, requiring proportionately less power to drive it (the lines being the same) at a given speed. Which of the two vessels would be the roomier, lighter, and more airy, as well as drier and easier in a sea way, we need not stop to discuss, although the subject is one to which we shall return.

THE ÆSTHETICS OF CONSTRUCTION.

From a paper read before the Liverpool Architectural Society, by Mr. G. F. Deacon, C. E.

The subject of this paper is the consideration of the conditions under which we are pleasurably impressed by the presence, in our structures, of those natural laws with which we have become familiar, in a greater degree perhaps than we are prepared to believe, by the senses of sight and touch; and not of necessity by that higher mental power which analyzes mathematically the action of these laws. I only speak of the absence of mathematical analysis in the minds of those for whom we build, and do not by any means suggest its exclusion from the minds of the builders. I have always believed that the distinction between the professions of the architect and the engineer is, or ought to be a distinction rather of degree than of kind. We are both of us constructors. We must investigate in common the resistance of materials to the simple strains; those, for instance, of compression, shearing, and tension; and we must, to become masters of our subject, be conversant, though perhaps in a different degree, with the more complex calculations arising from the combination of such strains, either in the same piece of a structure, or in pieces depending for their support upon one another. We must both of us consider, without prejudice, these elements in the works of eminent men who have preceded us, not with a view to servile imitation, but as a safe and well-tried foundation upon which to erect original, and it is to be hoped, better works of our own.

This cursory glance at the minimum amount of scientific knowledge which it appears to me we ought to possess in common, suggests the consideration of that particular branch of æsthetics included under the general term *decoration*, which is altogether independent of construction, and which is excluded from the more immediate subject of this paper.

Our scientific speculations, which are themselves subservient to the adaptability of the result to the end in view, having brought the design in which we are engaged to a certain point, we must, in carrying out our enterprise, and without in any way hiding the work produced by our reasoning faculties, exercise in a greater or less degree our imaginative faculties; often for the purpose of adding pleasing outline or relief, always with a view to the development of that intrinsic beauty which, as I hope to show, is rarely absent from scientifically designed structures.

Agreeable sensations arise in our minds from the contemplation of the beautiful in nature and the beautiful in art, from two distinctly different causes; the one depending solely upon our appreciation of the action of the mechanical forces of nature, the other affecting our senses in virtue of certain distributions of form, color, or light and shade, for which we can lay down but few rules, and those of a merely empirical nature.

Take in your hand a frond of the common lady-fern. It has, for some reason, a most pleasing effect on the eye, and you call it beautiful. Paste the same frond on a sheet of paper in a vertical position, and to most minds more than half its beauty will have vanished. And why? On the first impulse one would be inclined to answer, "because it formerly hung in a beautiful curve, and we have now rendered it rigid and straight;" but a little consideration will show the incompleteness of such a reply. The circle is a beautiful curve, so is the spiral, so is the cycloid; but the fern, when bent into any of these, will have but little more beauty than it had as a straight line. Only one curve will answer the purpose, and that is the curve into which it naturally falls, the curve in which the force of gravity is exactly balanced by the resistance of the stalk to flexure.

Innumerable examples of a similar nature might be adduced, and I think they would one and all show, "that there is a pleasurable effect produced upon the mind by forms resulting from, or balanced by, the direct action of the mechanical forces of nature, when those forces act in a manner which we apprehend intuitively, and are not complicated in their mode of producing their effect upon the senses by artifical means, or by the superimposition of one upon another." And this result is evidently altogether independent of the arrangement of the component parts—a division of the subject to which I have already alluded, as including all embellishments not necessary to those conditions of stability which the ordinary mind is capable of appreciating, but which may nevertheless be introduced to enhance the beauty of the structure.

The first of these effects appears to have a peculiar interest for the engineer, as it is the basis of a great problem; namely, how he is to produce, in those works which are pre-eminently dependent for beauty, on their lines of construction, such forms as the mind will at once apprehend as curves natural to the conditions involved, and which it will not be slow to call beautiful; in short, such curves as are known by engineers as lines of equilibrium. The second, or decorative effect, it is the more immediate object of the artist to produce, and in all cases it should be subordinate and subsidiary to the first.

For the purpose of illustrating my statements, or, I would rather say, as the best arguments that I can adduce, I have collected engravings and photographs of a few of each type of designs for iron bridges executed or proposed; and I have numbered these types, not according to their scientific classification, but rather as they produce a pleasing effect, or the reverse.

Type 1. Box and plate girders.
" 2. Lattice girders.
" 3. Bowstring girders.
" 4. Arched ribs with braced spandrels.
" 5. Suspension-bridge with stiffening girders.
" 6. The continuous parabolic system.
" 7. Simple suspension-bridge with vertical rods.

If we consider for a moment the disagreeable impression produced upon us by the first of these types (and every Englishman has ample opportunities for considering it), we cannot fail to notice that it does not altogether arise from the monotonous oblong form, or even from the flat uninteresting face of the structure. Cover it with moldings and ornaments of cast iron—paint it in the best taste—decorate it as you will—you cannot redeem it from its uncompromising ugliness. And why? Because it appears to be out of place; it is a form which seems to want some additional support; it is essentially deceptive. We cannot appreciate the beauty of construction, the principles of which we do not instinctively comprehend. In a limited sense those principles are correct enough. In the molecular structure of every straight beam there are curves of direct tension and compression, which clear up the mystery at once. The lines of compression are concave downwards, those of tension concave upwards. They cross each other in every case at right angles, and each cuts the neutral surface of the beam at an angle of 45°.

Although the two halves are in all respects similar, there are not two points in the half elevation of the web and flanges, at which the stress is at once the same in amount and direction. Along each individual curve the stress varies from center to end, and every curve represents an amount of stress differing from that of every other. Then what an infinitely complicated piece of workmanship we should have if we attempted to vary the section of our wrought iron plates, in proportion to the duty that each point in their elevation has to perform. Practically we cannot do this. It is for the engineer to determine how far he can approximate to the theoretical conditions involved, and thus save material without necessitating more labor than the value of that material represents; and in most cases this can be done with great advantage. In small wrought iron girders we may, perhaps, by due attention to the principles of stress, save fifteen per cent of the material necessary in a girder of equal strength, but of uniform section, and that without adding to the labor in the least. This percentage, however, is but a fraction of the weight which theoretical perfection represents as lost.

This type, then, is essentially bad in respect of its response to the theoretical conditions of a minimum weight of material. Nevertheless, in small spans the economy of labor consequent on simplicity of construction often compensates for this defect.

Type second is the straight lattice girder; and here the lines of stress are guided from their natural curves, and concentrated in the flanges and diagonals. This fact, however, does not assist the mind in conceiving the mode of action of the beam, and I am inclined to think that all the superiority of appearance is to be traced to the decorative effect produced by the open lattice work, and the reduction of apparent weight. Among the best known bridges of this class are, in England, those at Crumlin and Runcorn, and on the Continent those over the Rhine, at Cologne, and at Kehl, near Strasburg, and that over the Vistula at Dirschau. But one and all of these must be regarded as failures in an æsthetic sense. Probably Mr. Baker's towers at Runcorn, and the piers at Dirschau, are most in keeping with the works. The Gothic piers of the bridge at Kehl have a singular effect. Their appearance is very striking, but they do not harmonize well with the long horizontal lines of the girder, or with its lattice bars arranged at angles of 45°. The proximity of Strasburg Cathedral, too, is not calculated to impress one in favor of that puny cast iron architecture.

The bowstring girder is our next type, and it includes all those in which the top or bottom flange, or each, consists of a segmental or parabolic rib, connected together by diagonal lattice bars. The best known of those which have both flanges curved are Brunel's bridge at Saltash, and that over the Rhine at Mayence. All these structures are, as regards the iron work, more natural than either of the preceding types, and we must accord to them the merit of giving us the first clear idea of the manner in which they do their work. We may not feel satisfied with their appearance, but we must admit that it is, or may be made, much superior to that of either of the straight types.

We now come to the arch, respecting which I shall say more hereafter, but assuredly we cannot hesitate to assign to it, in our classification, a higher place than we would to those already mentioned. The mind at once perceives the natural and efficient manner in which it supports the load to which it is subject.

Our fifth type is the suspension bridge, stiffened in such a manner by lattice work as to be capable of bearing, without undue vibration, heavy rolling loads. It is sufficiently obvious that the effect of the simple parabolic or catenarian curve is, in a great measure, marred by the proportions of the stiffening girder.

In the late Paris Exhibition were exhibited two striking drawings, by Herr Carl von Ruppert, for bridges across the Bosphorus, and over one of the greatest chasms in the tertiary limestones of the Balkan. In carrying out the Austrian project of a railway to Asia Minor, it will be necessary to cross these places, and Von Ruppert has probably solved the difficulty in a very complete manner. It is well to mention that his investigations have been published, and they can leave no doubt in the mind of the reader that the Austrian engineer has brought together principles already well understood, with a boldness and originality resulting in a complete success.

There is but one more, and that is the pure suspension bridge. We cannot improve upon that simple catenary. Its mode of action is apparent at a glance, and its curve is evidently a natural one. But, unfortunately, we have no means of rendering it sufficiently rigid for railway purposes, without destroying its chief æsthetic characteristics.

Thus far I have endeavored to lead you through the general principles, in virtue of which each of the seven types supports its load. You may feel inclined to change the order of one or two, but that will not affect the general result.

Had I based the classification upon the relative economy of material, upon the absolute weight of the superstructure which each would have required for the same span, and to bear the same moving load, it is at least gratifying to know that the arrangment would have been precisely the same, and that, although in small spans the order of ultimate economy is somewhat changed by the different proportions of labor to material required, it would not be felt in the large spans.

These general facts have been long known to the engineer; but Mr. Benjamin Baker has recently reduced them to approximately correct figures for different lengths of railway bridges up to the limiting spans, and I have prepared, from his investigations, the annexed table, showing the weights of material in spans of 700 ft., and also in spans 100 ft. less than the limiting spans. The types are in principle the same as those I have described, though not arranged quite as Mr. Baker classed them.

I have now laid before you the general arguments which, you will probably admit, prove, at least in regard to great bridges, the truth of the statement that, in equal spans, the æsthetic properties of the lines of the structure vary in direct proportion to the simplicity of the design, in a scientific sense, and in the inverse ratio of its actual cost.

These results are sufficiently remarkable; and if we can in every case find beauty and science walking hand in hand, as here, shall we not be able to do more in the cause of both than we do at present? And this, I think, we can find in our works of stone and brick, without either the conditions of great size, or the cost of extra labor.

Table compiled from Mr. Baker's Analysis, showing the Approximate Weights of Wrought Iron or Steel in the Superstructure of Railway Bridges of six different types; the working stress of the iron being taken at 4 tons, and that of the steel at $6\frac{1}{2}$ tons per square inch of sectional area:

Description.	700 ft. Span. Approximate weight in tons.		Limiting Span minus 100 ft.	
	Iron.	Steel.	Weight of steel in tons.	Length of Span in feet.
Box girder	51,030	.....	....	.....
Lattice girder	17,360	4,410	27,315	900
Bowstring girder	6,650	2,730	68,055	1,300
Arched ribs with braced spandrels	3,500	1,995	364,420	1,900
Suspension with stiffening girder	3,045	1,715	276,450	1,900
Continuous girder with varying depth*	2,660	1,820	1,120,000	3,200

THE CORROSION OF BOILERS.

By Norman W. Wheeler.

The writer is induced to put forward a few crude thoughts in the hope that some competent chemist will experimentally determine whether his surmises are correct or otherwise.

The corrosion of boilers worked in connection with surface condensers is in great part attributed to a galvanic action induced by the condenser. But galvanic action does not establish itself spontaneously; some sort of chemical decomposition, or degradation of metals or other bodies being, so far as we know, a condition precedent, so that it becomes a question whether the corrosion observed is not the cause rather than the effect of the galvanic excitation observed.

When water is repeatedly vaporized and

* This type is nearly equivalent to Von Ruppert's system.

condensed, with very little exposure to the atmosphere, as is the case in practice, it becomes to a great degree deærated, but the question as to which of the numerous gases existing in natural water is first eliminated remains unanswered. If those gases, of which water absorbs the greatest bulk, cling to it with the greatest tenacity, a considerable part of the destructive effect is thereby accounted for. It is stated by good authorities that water absorbs at common temperatures its own bulk of carbonic acid, one twenty-fifth its bulk of oxygen, and still less of nitrogen. If, when water is deærated by heating, the neutral gas nitrogen is first expelled, the corrosive power of the water should be exalted by its atmosphere, so to speak, of carbonic acid and oxygen; and if, during the exposure to the air in the air pump and hot well, the water absorbs the gases in ratio of their supposed affinities, we should have in the boiler a pretty active solution of carbonic acid in oxygenized water, from which we ought to expect corrosion of the metal of lowest chemical rank exposed to its power, corresponding with the observed facts.

A case encouraging the belief in the seriate elimination and absorption of gases, occurred in the writer's practice in 1864. Four vessels were built for the Government, with return flue boilers and "high pressure" engines, but the steam was condensed, for the sake of fresh feed water, in open surface condensers; that is, condensers making no vacuum, but fitted with tubes and circulating pumps, and the steam spaces in the condensers communicating with the atmosphere through pipes. The condenser tubes were made of iron and galvanized, for the purpose of avoiding the corrosion of the boilers. The feed-water was drawn by the feed-pumps directly from the condensers. As a matter of convenience, the atmospheric pipes were led from the condensers and opened into the smoke pipes, so that when an exhaust took place, the vapor was for an instant driven out through the atmospheric pipe, and because of the continuous condensation, the gases in the smoke pipe were drawn back toward or into the condenser between the successive exhausts, thus keeping up a pulsation and swaying back and forth of vapor and gases in the atmospheric pipes, which, although made of copper, were eaten into holes in a few days. The pipes passed overhead through the fire rooms, and the continual dripping of hot water made those places very uncomfortable. The corrosion of the boilers was marked and unmistakable within a month.

The atmospheric pipes were then changed and led to the open air, and the corrosion of both boilers and pipes apparently ceased, and was not again observed while the vessels were within the range of the writer's observation.

It is supposed that carbonic acid was absorbed rapidly by the vapor and condensed water in the atmospheric pipes, the supply being derived from the gases of combustion, and the acidulated water passed into the boilers by the feed pumps.

Now, if it be proven that the water, while exposed in the hot well of an ordinary engine, absorbs oxygen and separates it from the nitrogen of the air, and that the nascent carbon of the oils, used to lubricate the internal parts of the engine, is seized by the oxygen when the oils are decomposed by the heat of the steam, we shall be able to account for an amount of carbonic acid in the boilers working in connection with common surface condensers, sufficient to destroy them rapidly.

WIRE ROADS.

From "The Engineer."

The great defect of the modern railway is, that the system does not admit of general use. It is true that a railway can be laid down and worked by locomotive power in almost any conceivable country, provided there is sufficient capital available for its construction, and sufficient traffic to pay for working it. But thousands of cases will present themselves to the engineer in which, although a fair amount of traffic may be expected, it is morally certain that this traffic could under no possible circumstances prove remunerative, for the simple reason that the capital expended would of necessity be out of all proportion to the money received for the carriage of goods or the conveyance of passengers. As we cheapen railways we increase their sphere of usefulness; and were it possible to reduce the cost of railways below that of common roads, and to render the conditions of working such, that on them, as on a canal, private individuals could run private vehicles, it is more than probable that common roads would cease to have existence, their place being taken by tramways or public railroads. Numerous attempts have been made to reduce the cost of railroads, but with, for obvious reasons, very little success. The cheapest single line of 4 ft. 8½ in. gauge, which it is possible to lay in an easy country will cost, at least, £3,000 per mile. If the country is difficult or hilly, the expense of construction may very well rise to ten times the sum. Railways represent the most perfect mode of transit yet produced in one sense, and it is therefore to be regretted that they are not more generally applicable to all the purposes of locomotion than is at present the case; but it is, we think, still more to be regretted that there is no prospect whatever that they will ever become much more useful than they are now. A good deal remains to be done as regards tramways, which partake intimately of the nature of railways without being railways in the truest or highest sense. But even when tramways have received that enormous development of which the system is probably capable, conditions will still constantly exist under which it will be impossible to resort to their use; and the same truth applies to the ordinary macadamized or graveled road. Stretching a point, every ordinary highway and parish road may be regarded as the substructure for a tramway. No tram can be laid on a substructure much worse than our third and fourth-rate country-roads. Therefore it may be taken for granted that where a road can be made a tram may be laid, and also that where a road cannot be constructed no tramway can be laid down. But in almost every civilized or partially civilized country in the world, circumstances occur under which, though means of transit are required, it would be impossible to provide them, either in the shape of railroads, tramways, or common roads, at a price which would justify their construction even by a state, much less by any company of adventurers. Therefore it appears that the proposition with which we commenced this article applies to both tramways and common roads as well as to railways, though not with the same force; for both tramways and common roads are open to objections, which do not exist in the case of railroads, far more serious than the want of universal adaptability.

It has long been felt that some efficient means of transit, which might be used under any conceivable conditions, are badly wanted; but it does not appear that much had been done up to a very recent period to supply the want. The popular way out of such a difficulty as that, for example, which presents itself when the ore from an out-of-the-way mine has to be got to a seaport, lies in making a road, buying carts and horses, building stables, and hiring carters; where it happens—and in the colonies it does happen rather often—that no road fit for wheeled carriages can be made, the popular remedy fails of course. There are two substitutes for common roads; one consists of mules and the other of camels. Coolies and elephants we will leave out of the question for the present. Now mules are no doubt very useful, and so are camels; but any of our readers who has had to transport a 20-horse engine, for example, up country on the backs of mules or camels, will agree with us that, although the muleteer of song is a very picturesque creature, the muleteer of fact is, though picturesque, something else as well; and, making the best of mules and camels and their drivers, the great fact still remains, that they carry things slowly, and cost a great deal. In a word, mules and camels no more solve the problem of transport in distant lands, as English capitalists and engineers would have it solved, than a trained hippopotamus, weighing about four tons, and carrying a couple of Kaffirs, represents a perfect means of ordinary locomotion. It would not be easy to estimate the loss which accrues each year to our colonies as a consequence of the want of some means of bringing produce to market. There are coffee plantations in Ceylon, more than 40 per cent of the produce of which is constantly wasted and lost, simply because no efficient means exist of getting the coffee to market down the jungle-clothed sides of hills. The waste and loss of cotton in India, for the same reason, is enormous. In Namaqua land, again, there are valuable mines which cannot be worked because coal costs £8 per ton—half this expense, or more, being incurred in transporting it a few miles up the country on the backs of mules. It is impossible to estimate, indeed, at this moment, how much wealth is lost to the world because no means exist of transporting cotton, and coffee, and ores, and coal, over moderate distances at moderate rates.

Impressed as we are with the importance of this loss, and desiring as we do to see the loss for ever done away with, we have carefully watched every attempt that has been made of recent years to overcome the difficulty. The narrow gauge railways of Queensland; Mr. Brunlees' cheap lines in

South America; the pneumatic dispatch—in which there is more as a means of cheap transit in difficult countries than is at present perceived—these things, and such as these, holding out promise of future good, have all claimed our attention; but very little observation is sufficient to show that they none of them comply with the conditions of the greatest difficulty. Take the case of a coffee plantation in a fertile district on the side of a hill; between it and the nearest port, or the nearest road to a port, lies an impenetrable jungle, deep ravines, and water courses now dry and anon filled with a foaming torrent; the railroad can do nothing for such a case, the pneumatic dispatch is of as little value. What the planter wants is the wings of the dove to take him to the uttermost part of the sea. If he could but fly! If he could but organize a trained troop of flying steeds to take his produce bit by bit over the top of the jungle, across rock, ravine and torrent, then, indeed, the problem would be solved, and the flying steeds would serve a more useful purpose, and do more good than ever Pegasus has done yet.

Now, is this flight impossible? Are the difficulties to be encountered insurmountable? We think not. We have spoken of flying steeds, and we have done so with a purpose. It is evident that if we could construct a road above ground instead of resting on it, neither jungle nor forest need give us trouble. There is a race of pirates in Borneo who live in forests. These people seldom touch ground. Their roads consist of single trunks of trees felled, laid end to end, and carried on suitable uprights for miles through the depth of the forest from the sea shore. The jungle undergrowth is impassable, therefore those people make their road over it. We are all familiar with the rope bridge of South America, across which the traveler is drawn in a basket swinging below the bridge, which consists of a hide cable. In these two, the Borneo tree road and the South American bridge, we have the crude germ of an idea which, properly worked out, may do wonders for the good of mankind.

The only scientific development of the idea yet before the public is Mr. Hodgson's wire railway at Bardon Hill, Leicester, already noticed in our pages.* This line, three miles long, extends from Messrs. Ellis and Everard's granite quarries at Markfield, to Bardon station on a branch of the Midland Railway. At Bardon is a tremendous rotatory crushing machine, capable of converting a couple of hundred tons or so of granite into road metal per day. We need not again describe the wire line put down to transport 100 tons of stone per day to this machine, but never as yet worked up to its full capacity. It will suffice to say that the principle involved consists in suspending a wire rope on wheels fixed to posts placed about thirty-one to the mile, just as are ordinary telegraph posts. The rope runs over a horizontal pulley of considerable diameter at one end, and at the other round a $4\frac{1}{2}$ ft. Fowler's clip drum, driven by a 16-horse portable engine, which is not half loaded. One side of the six miles of endless rope is always traveling toward Markfield, the other side away from it, toward Bardon. The stone is loaded into boxes, which are hung on the rope and run full to Bardon, where they shunt off the rope, are emptied, and sent back to Markfield on the return line. The wire road winds in and out, passing here through a grove, there across pasture lands. In one place it jumps obliquely across the high road with a span of 600 ft. clear. The pace at which the buckets travel is about four miles an hour, the load in each about one cwt., and some thirty buckets come to the mile. The line has now worked for some months most successfully, and we are pleased to hear that in Italy, Spain, and Turkey the system is likely to be extensively adopted. The system is certain to prove infinitely valuable to countries perishing from that inanition due to want of means of internal circulation.

Here we have means of transport provided, by which all obstacles connected with the country are avoided. No doubt objections may be raised to the scheme, and difficulties are certain to be encountered in carrying it out on a large scale. One or two points, however, are certain; it has been proved that the principle can be applied in practice; wire-rope railways are very inexpensive—£150 to £500 per mile; they offer the only certain solution for hitherto insurmountable difficulties, and, lastly, the entire principle is correct. We did intend to speak of the mechanical questions involved, such as the best means of carrying the rope, putting on the buckets, the power consumed, etc.; but these we think best, after all, to speak of at a future

* See "The Engineer" for February 19, 1869.

time when the system shall have been more fully developed, and some inquiry shall have been made into its dynamics. So far the scheme is a mechanical success, and that is about the only point connected with it, save its all but universal applicability to the purposes of transport, with which we have anything to do.

RAISING WATER FROM MINES.

From "The Engineer."

In scarcely any department of the operations necessary to bring our subterranean treasures to the surface, is there greater diversity of comparative working cost than in the process of freeing the mines of water. The men who win our metals have made much more progress in this department than those who get our fossil fuel, as we shall presently see. Meanwhile let us get some idea of the financial significance of the subject by remembering that from the northern coalfield comprising Northumberland and Durham there has every year to be taken water fifteen times the weight of the output of the coal of the district, which, according to the the mines inspectors' last returns, reached, in 1867, a total of 26,500,000 tons. In Staffordshire the water raised is computed at ten times the weight of the coal; but the ratio of cost in each may be assumed to be alike. It is estimated at .343 pence per 1,000 gallons raised 100 ft., or, in other words, per million foot-pounds. This calculation is made upon the basis that the average of the lifts is 384 ft., which is computed to be the average depth of the pits in South Staffordshire; and this, for the purpose of calculation, may be taken as the depth in the northern field. Computed on the quantity of coal raised in 1865, the cost of pumping in the South Staffordshire collieries is estimated by Mr. E. B. Marten at £100,000 a-year, taking £500,000 as the capital employed, and allowing a 5 per cent reduction on this capital. The engines are presumed to work twenty-four hours per day. Taking Mr. Marten's figures for his guide, and adapting them to the 25,000,000 tons raised in the northern district in 1865, Mr. William Waller puts down the yearly cost of pumping the Northumberland and Durham district at £459,200.

How much more this is than need be, may not be accurately concluded, but may, to some slight extent, be imagined from a fact which Mr. Warington W. Smyth has placed upon record. It is that he has watched a large pumping engine in the north which raises water from 105 fathoms deep, in 12-in. lifts, at seven and a-half strokes per minute, with a consumption of twenty to twenty-five tons of slack per day, whilst a similar amount of work is done by a Cornish engine with from two to two and a-third tons. The coal was no doubt inferior in the former case, but the result, he intimates, shows that there are engines in the country consuming upwards of ten times the quantity of coal that is needed for the work accomplished. It is clear that the pumping at our coal mines is not conducted as cheaply as it ought to be, and we have reason to know that even the metal mines of Cornwall might be freed for less money than is now the current charge. What should be the cost of raising 1,000 gallons of water 100 ft.? Mr. Wm. Waller set himself to answer this question in a paper which he communicated to the North of England Mining Engineers during 1857. By the side of the figures as to the assumed average cost in the north of England and in South Staffordshire, he places data obtained under his own observations relating to waterworks. Should any one object that these are not parallel cases, he submits that the mining engine works under more advantageous circumstances; for this reason, that being necessarily in the first instance sufficient to reduce the water, afterwards in keeping it at the reduced level, it is working well within its power and under very economical conditions; whereas, the waterworks engine, having to contend with ever-varying demands, with extra and intermittent exertion, with increased friction and resistance in restricted pipe area, is under every disadvantage. For the purpose of comparison, however, colliery and waterworks engines may be considered as working under similar circumstances.

A most important difference in the duty of several engines in the same undertaking sometimes transpires. This is especially seen in the case of the East London Waterworks Company. It is stated on the authority of Mr. Wicksteed himself that the total cost of lifting a million foot-pounds, taken on the average of several years with different engines is: Single-acting engine, Boulton and Watt, .543 pence; double-acting engine, Boulton and Watt, .358 pence; double-acting engine, Boulton and Watt, .333 pence; Single-acting Cornish, Harvey and Co., .150. Whilst the water company are supposed to give 7s. 6d. a ton for their coal, the average of the East London was 10s. 6d.

The Southwark and Vauxhall Company's total cost is at 10s. a ton for coal, .084 pence; or with five-sevenths for labor, repairs, wear and tear, etc., .144 pence.

The Grand Junction, with coal at 14s. 6d., is set down at for coal alone, .192, while labor, etc., added .276 pence.

The Liverpool Corporation Works present a comparison more nearly approaching the general pumping arrangements of a colliery's engines—both the ordinary crank engine and Cornish type are used; and the cost of pumping is given with great detail and accuracy. There are in Liverpool seven stations with nine engines. At the Bootle station there were three engines, each with beam and crank, and a single-acting bucket pump, and worked direct from the beam of each engine. Only two of these engines were worked together, and they delivered through an air-vessel. At the Bevington Bush station there was a bucket-lift, but it was altered to a plunger, and at once the total cost fell from .789 pence to .201 pence per million foot-pounds. Most of the calculations are based upon the returns for 1849; but, as indicative of the great saving to be effected by a large amount of duty performed, we may state that the engine at the Green-lane station of the Liverpool Company, which is Cornish, with a 56 in. cylinder, and a 9 ft. stroke, by Harvey and Co., which raised 992,000,000 gallons 100 ft. at a total cost of .222 in that year, was raising in 1865 as much as 2,736,000,000 gallons that height, at a total cost of .178 pence, the cost of the coal used being 6s. 10d. ton. And when the Southwark and Vauxhall raised 4,061,000,000 gallons, with coal at 10s. a ton, they did it at a total cost of .144 pence per million foot-pounds. The cost of coal alone at the Green-lane Liverpool engine was .075, and at the Southwark and Vauxhall, .084.

Hence it is concluded that the cost of coal for lifting 1,000 gallons 100 ft. high, or a million foot-pounds, need never exceed one-eighth of a penny where Cornish engines of the best make are employed; and that the total expense, exclusive of the interest of capital for doing this amount of work, might be within one farthing, instead of two or three farthings, which it often is.

"The Engineer" then discusses the South Staffordshire drainage, which is now a tax on the coal raised of 4½d per ton.

STRENGTH AND RESISTANCE OF MATERIALS.—In a paper "on the present state of knowledge of the strength and resistance of materials," read before the Institution of Civil Engineers, May 11, 1869, Mr. Jules Gaudard stated that the theory in the case was closely connected with that of molecular mechanics. But being a branch of that science altogether of practical application, it required only to borrow from scientific theories the principles on which to base rules of construction, simple enough to be of general application and yet sufficiently exact to be used with confidence. The formulæ of strength brought into view, on the one hand, the destructive action of external forces, and, on the other hand, the resisting power of the molecules of the material. External forces were of two kinds: one kind comprised elements directly given, such, for example, as weights; the other kind consisted of reactions—functions of given forces. In certain cases these reactions might easily be found by the science of statics alone, as, for example, in the case of a beam placed on two supports; in other cases they would depend on the changes of form of the solid. It was this, for example, which caused the difficulty of calculation in arches and in continuous beams of several spans. Or, lastly, it might happen that the body in question might not be in a state of equilibrium, but that its particles might oscillate under variable dynamic influences, or forces of inertia. This was the case of concussions, vibrations, etc. These various external forces being determined, it would easily be seen if they tended to cause certain parts of the solid to elongate, or to shorten, or to shear, or to turn round certain axes. These various effects, extension, compression, sliding, torsion, flexure, might further manifest themselves separately, or might combine with each other. Under the action of these forces, the body would necessarily be changed in form; for solids perfectly rigid were only pure abstractions. The study of these changes of form constituted the object of the theory of elasticity. The study of strength, or resistance, had to do with the power which the solid, according to its physical constitution, possessed to maintain, if not its form, at least the cohesion of its parts.

The author then proceeded to consider the forces of various kinds to which materials were subjected, such as extension, compression, sliding, flexure, torsion, and shearing; and in reference to all these, he gave the results and formulæ of the most modern investigations; expressing them at such length as to make them intelligible, but with sufficient conciseness to bring them within reasonable limits of space.

In conclusion, it was remarked that the theory of the strength and resistance of materials touched obscure problems relating to the physical constitution of bodies, and yet its practical character obliged it to be simple. Another motive, also, justified the departure from rigorous exactness, that was, the irregularity of the materials facts; if it was good, in effect, to associate mathematical science with physical phenomena, it was incontestable that these two elements, one always logical, the other frequently capricious, were often separated from each ether.

In spite, however, of these imperfections, the theory of the strength and resistance of materials in its present state constituted an elegant and useful doctrine, which ought to be better known by the majority of constructing engineers, so much did it tend to impress boldness and elegance on designs of all kinds. In any case, the theory, imperfect though it might be, had the great advantage of generalizing facts. Empiricism, if left to itself, would encumber the science of construction with a mass of rules, without reason or connection, well calculated to repel and mystify practical men.

Improved Road Roller.—Gen. Green, of the Croton Aqueduct Department, New York, has introduced a roller consisting of a series of independent discs some $1\frac{1}{2}$ in. thick (that is to say, $1\frac{1}{2}$ in. wide on the tread), and a series of alternate discs of the same width, but of 3 in. less diameter, all mounted on a common shaft, so that the whole roller is grooved like the roll of an iron mill for producing $1\frac{1}{2}$ in. square iron. As each disc moves independently on the shaft, facility of turning and avoidance of scraping while turning, are the result. But the most important result—and it is very important—is the increased hardness and *uniformity* of the road. A long solid roller can hardly be made heavy enough to crush down the protruberances of the surface; hence soft or uneven places are left between them. The grooved roller easily cuts into hard and projecting places, pressing the material laterally as well as vertically, so that the hollows are filled and the material is uniformly condensed.

THE COMPUTATION OF EARTHWORK.

From "Engineering."

We have, from time to time, illustrated and described several different arrangements for the mechanical computation of earthwork, by which the long and tiresome operation of calculating the cubic contents of the cuttings and the embankments of a railway can be substituted for a process of simple inspection, so that the quantities can be registered expeditiously, and with a minimum chance of error. A very ingenious instrument has recently been designed by Mr. W. H. Barlow for this purpose, and which will be found invaluable for making the computations necessary for framing parliamentary estimates, as well as for the more precise earthwork calculations during the progress of actual work. The instrument consists of a wooden circular tray, about 12 in. in diameter, in which are set cardboard discs revolving round a central pin fastened in the tray, and having engraved on their peripheries quantity scales of relative proportion. Upon the edge of the tray is screwed a brass stop, terminating in a flat finger, with a feather edge on one side and a zero inscribed upon its end.

The cardboard scales are of two classes, the height scales, referring to cuttings or embankments, ranging in height from 0 to 75 ft. These are engraved upon the larger disc, which entirely fills the tray, but can be turned round within it upon the center pin; the zero of this scale, in operating the instrument, is made coincident with the feather edge of the brass finger. The other is called the quantity scale, and is applicable for all widths and slopes of the height scales; it is graduated around the complete circle, and represents a total of 100,000 c. yards. This disc. is about 1 in. smaller in diameter than the outer one, which it overlies, and turns freely upon its center; its zero corresponds with that on the end of the brass finger. There is space sufficient upon that part of the under disc exposed beyond the edge of the upper, to allow of four or five height scales being drawn upon it. All these scales, by preference, refer to one formation width, with varying slopes; separate cards being prepared for different widths, and which can be easily placed on the tray by unscrewing the stop and lifting off the upper disc.

Both the height and the quantity scales are but the ordinary earthwork tables graphically stated. In constructing the former, the calculated cubic contents of a bank or cutting, of a certain formation, width, and side slope, forms the extent of the scales, each of the subdivisions of which represent the quantity contained for heights decreasing foot by foot to nothing, a constant length of 66 ft. being maintained, although, if desired, the scale may be divided into shorter lengths. These graduated quantities being thus drawn, are projected with ease upon the circular scales of the disc, and from which the standard quantity scale can be laid off.

In using this instrument, the height scale adapted to the intended slopes and formation width is selected, and its zero is accurately placed against the feather edge of the brass stop by means of a pointer; the disc is then fastened into its position by set screws. Then the zero of the quantity scale, free to revolve, is accurately adjusted to the 0 at the end of the brass stop. The longitudinal section having been divided into chain lengths, a steel pointer is placed on the rim of the quantity scale exactly opposite to that division on the height scale, which corresponds with the height or depth at the first chain. The disc is then brought round until the pointer touches the brass stop. Proceeding in this manner with each chain length in the bank or cutting, the total quantity may be read off on the quantity scale at the zero of the brass finger, provided the quantity does not exceed 100,000 c. yards, which is the total capacity of the complete graduated circle. If the whole contents, therefore, exceed 100,000 cubic yards, that amount must be added to every complete revolution of the quantity scale. It is obvious that the use of this instrument can be extended to computing the quantities to be added or deducted for any formation widths for which height scales are not provided; if the earthwork be first measured up with one base, and afterwards with a smaller one, the difference between the totals will give the cubic contents of a bank or cutting, with a formation width equal to the difference between the two bases used in the computation. This quantity divided by the width will give the cubic contents per foot of formation.

Although as designed no means are provided for computing the contents of banks or cuttings upon sidelong ground, it is obvious that this could be effected by a modification of the quantity scale, which could be adjusted to correspond with varying transverse slopes.

Altogether this instrument is the best adapted for its purpose that we have seen, and we are the more glad to bring it into prominent notice as Mr. Barlow proposes to devote any profits arising from its sale to the Benevolent Fund of the Institution of Civil Engineers.

GUIBAL'S VENTILATING FAN.

From a paper read before the Institution of Mechanical Engineers, by Mr. J. S. E. Swindell.

The fan employed at the Homer Hill Colliery, Cradley, has eight vanes, and revolves on a horizontal shaft within a cylindrical casing of brickwork, by which it is completely enclosed at the sides and circumference, with the exception of a circular aperture in the center of one side for the entrance of the air from the mine, and an outlet opening in the circumference for the discharge of the air into the outlet chimney. The area of the outlet opening is regulated by an adjustable sliding shutter, according to the extent of ventilation required; and the outlet chimney is built with a gradually increasing area up to the top, so as to reduce the velocity of the air at the point of discharge, and thereby prevent the loss of power that would occur in discharging it at the velocity of the fan. The fan is driven direct by a horizontal steam engine working a crank on the end of the fan shaft without the intervention of any gearing. The fan is $16\frac{1}{2}$ ft. diameter and $4\frac{3}{4}$ ft. width, and its usual working speed is 26 revolutions per minute, discharging 13,500 cubic ft. of air per minute; and it can be got up in only about one minute's time to the higher speed of 96 revolutions per minute, discharging then 51,700 cubic ft. of air per minute. The current of air from the mine passes to the ventilator along an inclined drift leading off from the upcast shaft at a little depth below the top; and the top of the upcast shaft is closed by a movable cover, which is lifted by the ascending cage on arriving at the top, the weight of the cover being counterbalanced by weights. This is the first mechanical ventilator that has been applied in the working of the South Staffordshire Thick or Ten-Yard coal; and it has now been running about nine months, without a single stoppage for repairs of any description, and is doing excellent work, the total cost of the fan, with engines and connections, being only about one-third of that of an ordinary ventilating furnace for producing the same amount of ventilation. A comparison of actual working between the furnace and the fan at a colliery in the north of England shows that with a consumption of only two-thirds as much coal, the fan supplies nearly double the amount of air obtained with the ventilating furnace. Several of these ventilators are now at work at collieries in different parts of the country, some of which are as large as 30 ft. diameter and 10 ft. width, capable of delivering 100,000 c. ft. of air per minute; and they are so free from liability to get out of order that no accidents of any consequence to the ventilation have occurred with any of them.

ILLUMINATING POWER OF COAL GAS.

From a paper on "Experiments on the Standards of Comparison Employed for testing the illuminating Power of Coal Gas," read by Mr. T. N. Kirkham, M. Inst. C. E. before the Institution of Civil Engineers.

It was observed that the standards of comparison at present in use were known to be wanting in that uniformity of result necessary for determining with accuracy the difference in the intensities of two lights. But as the amount of the variation had never been clearly defined, the author had instituted a series of experiments for the purpose of ascertaining the extent of these differences.

The instruments employed for testing the illuminating qualities of two flames were founded on the law of optics, that light diverging from a luminous centre diminished in intensity in the ratio of the square of the distance. This principle had been taken advantage of by Count Rumford in the instrument known as the "Jet Photometer," which was described; as was also another method, suggested by Professor Bunsen, which was dependent for its action upon the combination of reflected and transmitted light.

In France, the instrument employed was M. Foucault's modification of that proposed by Count Rumford, as arranged by MM. Dumas and Regnault; while the standard of comparison was the amount of light emitted from grammes of colza oil, specially prepared and verified, burning in a Carcel lamp, of certain fixed proportions, at the rate of 42 grammes (648 grains) per hour; and it was required that the light produced by from 25 litres to 27½ litres (.8625 to .9707 of a cubic foot) of gas, consumed in a Bengel burner of known dimensions, should be of equal power. The mode of conducting an experiment with this instrument was then detailed; and it was explained that during the progress of the experiment, the quantity of gas was regulated, so that the two lights should be maintained of equal intensity. In this way it was possible to compare the consumption of oil with that of the gas, and if the lamp had burned at the specified rate of 42 grammes (648 grains) per hour, the experiments should have been completed in 14 minutes 17 seconds.

In England, the instrument in use was constructed on the Bunsen principle, and the standard of comparison, as defined by Act of Parliament, was a sperm candle, burning at the rate of 120 grains per hour. The gas being consumed at the rate of 5 cubic feet per hour, through an Argand burner having 15 holes, and with a chimney 7 in. high, must be equal, in intensity of light, to 12 such candles.

The instrument by means of which the experiments were made by the author was also constructed on the Bunsen principle, combining all the most approved modifications. It consisted of four photomers, radiating from a common centre in the form of a cross, and each accurately scaled, adjusted, and fitted with every appliance to insure uniformity and precision.

The first series of experiments was undertaken for the purpose, if possible, of arriving at the amount of variation in the illuminating power of candles obtained from the principal manufacturers. Gas was adopted as a standard of comparison; and to insure uniformity in its illuminating power, a sufficient quantity for carrying out the experiments on each occasion was put into a gasholder in the labaratory, the temperature in the latter being always maintained at 62° Fahrenheit. In this series, each of the four photometers was supplied with candles of a particular make, to the use of which it was restricted throughout the day, every successive experiment being made with a separate specimen. All the candles were cut in half and burned from the centre. It was observed that, although the standard candle was fixed by Act of Parliament, as a sperm candle, of six to the pound, burning uniformly at the rate of 120 grains to the hour, yet no such candle was to be obtained; for from various quantities of sperm candles, six to the pound, procured from several manufacturers, the average rate of consumption was 135 grains. This fact had been previously demonstrated by the extended series of experiments carried out by Professors Graham, Leeson, Brande, and Cooper, in 1852. The Parliamentary rate, being abnormal, was so rarely met with, that all operators had been compelled to make corrections for these variations, and had unanimously adopted the ordinary rule of simple proportion for the purpose. It was proposed, therefore, in the analysis of the diagrams exhibiting the results of the experiments, that the candles burning at the rate of 135 grains should be designated "normal standard candles," to distinguish them from the Parliamentary standard of 120 grains.

Commencing with experiments Nos. 56 and 58; in No. 56 with a consumption of 119 grains, the illuminating power of the standard gas was represented as 15.3 candles; whilst in No. 58, with a consumption of 121.2 grains, it was 14.5 candles. The difference between these two experiments, made with candles which happened to be nearly within the Parliamentary standard, was .8 of a candle. In experiment No. 51, burning the normal standard quantity of 135 grains, the same gas was represented as being 15.48 candles; and in No. 61, consuming 134.4 grains, or .6 of a grain less, it was 16.28 candles, the difference being in this case also .8 of a candle. In experiment No. 60, with a consumption of 134.7 grains, or only .3 of a grain more, the gas was shown to be 18.18 candles, a difference of 2.70 candles in experiment No. 51, with a consumption of 129 grains of sperm, the gas had illuminating power 12.6 candles. In experiment No. 52, with a consumption of 145.2 grains, the gas appeared to be 12.6 candles. Experiment No. 52, with a consumption of 157.2 grains, gave the gas as 12.54 candles. The last three experiments were examples of candles consuming different quantities of sperm, yet giving practically the same amount of light; the correction of which to the Parliamentary standard of 120 grains created error. Experiments Nos. 57 and 54, each with the same consumption of 130.2 grains, showed the difference in the illuminating power of the gas to be 2.42 candles; the former representing it as 13.02, and the latter as 1544 candles. These were examples of candles burning the same quantity of sperm, yet giving a different amount of light. The greatest difference in the illuminating power of the "standard gas as shown throughout the forty-four experiments made upon this day, was 4.60 candles; being between experiment No. 51, with a consumption of 129 grains, giving an illuminating power of 13.58 candles, and experiment No. 60, consuming 134.7 grains, representing the gas to be 18.18 candles.

An examination of the various diagrams would demonstrate, that the differences in the candles might be classed under five heads; viz., First. Differences in the illuminating power of Parliamentary standard candles, burning at the rate of 120 grains per hour. Secondly. Differences in the illuminating power of normal standard candles, burning at the rate of 135 grains per hour. Thirdly. Candles with different rates of consumption, giving the same amount of light. Fourthly. Candles with the same rates of consumption, giving a different amount of light. And fifthly. Greatest differences of illuminating power, in the whole number of experiments when corrected to the Parliamentary standard.

From the tabulated results of three other sets of experiments, it appeared that, in the first, when the consumption of sperm varied from 109.2 to 134.4 grains, the greatest difference in the illuminating power of the gas, corrected to the Parliamentary standard, was 4.59 candles; in the second, when the consumption ranged from 120.9 to 130.8 grains, the difference in the illuminating power was 3.06 candles; while in the third, with a consumption of from 120 to 142.5 grains, the difference was 4.21 candles.

The second, third, and fourth series of experiments were made with candles obtained from one manufacturer only. As an example of the results arrived at by the second series, it was stated that with a consumption of sperm varying from 129.6 to 130.2 grains, the greatest difference in the illuminating power was 2.26 candles.

Third series of experiments was made for the purpose of ascertaining whether the French standard of comparison, when used at a photometer on the Bunsen principle, was more reliable than the candle. It was thus found, that when the lamps were allowed to burn without any regular system of trimming, the variations were about as great as those of the candles; but when the lamp was trimmed before the commencement of each experiment, the variation was about the same as with the best candles. It was probable that the result would have been better, if the time allowed for taking the observations had been fifteen minutes instead of ten minutes; for the lamp when filled weighed 10 lb., and the balance employed would not turn to less than a grain. Subsequent experiments corroborated this supposition. Of this series the examples selected showed, in one case, that the greatest difference in the illuminating power of the gas was 1.69 candle, with a consumption of sperm ranging between 136.5 and 124.5 grains. In another case the greatest difference in illuminating power, corrected to the standard consumption of 108 grains of oil in ten minutes, shown in the whole number of experiments, was 2.3 candles, when the time required for the consumption of 108 grains of oil by the lamps was respectively 9 minutes 39 seconds and 10 minutes $3\frac{1}{2}$ seconds.

For several years past the author had had in operation one of Mr. Lowe's jet photometers, for the purpose of indicating the illuminating power of the gas as it was being manufactured. As its apparent accuracy seemed to promise a more reliable means of determing the illuminating power of gas, it was decided to carry out a fourth series of experiments, with a view to discover the relation between the indications of this instrument and those of the French and English standards. At the "Cross" photometer, three consecutive experiments were made upon the quality of the gas, compared with four candles burning at the same time. The results of these twelve experiments were then averaged, and accepted as the illuminating power of the gas in each case. Another operator was at the same time engaged at the Dumas and Regnault photometer, and the average of these experiments was also taken as representing the illuminating power of the gas. Two of Mr. Lowe's jet photometers, fitted precisely alike, were in operation throughout these experiments; the orifice in each jet being of the same size, so that at any given pressure the height of the flame from each would be the same. The pressure at the point of ignition was regulated so as to give a flame exactly 7 in. in height and that pressure was duly recorded. The height of the flame at a pressure of .6 of an inch was also observed, as well as the time required for the issue of .1 of a cubic foot of gas under each of these pressures.

A diagram was prepared, showing the results of simultaneous experiments for ascertaining the illuminating power of different qualities, by two different systems, as at present existing, and by the proposed plan of testing by the jet. On this diagram a diagonal line had been drawn, which illustrated the theory of ascertaining the illuminating power of gas by means of the jet photometer, worked on the "Retrograde system," which might be thus stated: Maintaining a 7-in. flame from an orifice of certain fixed dimensions, the illuminating power of the gas was in direct proportion, inversely, as the pressure.

This diagonal line being considered as the "standard 7 in. flame," according to the theory just advanced, it was observed that the average results of twelve experiments very nearly coincided with the theory; and at pressures of .40, .51, .63, .64, and .68 of an inch this was especially the case. The highest and the lowest candle experiments were completely cut by the line, and the lamp experiments also tended generally to prove the theory.

Another diagram, representing the duration test corresponding with the retrograde scale, showed the time required for the issue of .1 of a cubic foot of gas, of a certain illuminating power, maintaining a 7 in. flame from the jet photometer. The use of the duration test was to check the working of the jet photometer, and to afford a means of discovering any irregularities that might occur in the apparatus. As an example of its use, it was seen by the retrograde scale that gas having an illuminating power of 14 candles gave a 7 in. flame at a pressure of .63 of an inch; and upon referring to the duration test it would be found that .1 of a cubic foot of gas of that illuminating power ought to maintain that flame for three minutes. Should there be any considerable deviation, it was an evidence of some derangement in the apparatus.

From these experiments the author believed it was evident that a more reliable method than that at present in use for determing the correct illuminating power of the gas supplied to the public was urgently needed; and he thought the following system would be found to give results approaching as nearly as practicable to a truthful estimate: Let the illuminating power of the gas be determined by the aid of the present recognized photometer, fitted with a Carcel lamp, burning oil of the same quality, and verified in the same manner as that adopted by the municipality of Paris as a standard; and let a sufficient number of experiments be made so as to cover the errors that were known to exist, and the average of these be compared with the illuminating power, as shown by the jet photometer and the duration test, and then the "mean of comparison" might be taken as the illuminating power of the gas.

ENAMELING AND POLISHING.

From "The Art of House Decoration," by Mr. Sutherland.

In speaking of enamel, it must be understood as polished paint on the surface of woodwork, such as doors, architraves, window shutters, etc., etc. Enameling and polishing is an art which requires the exercise of the greatest care and patience in its execution. A little carelessness or inattention at the finish may undo the work of days. The work will not bear any hurry, either in the material or labor, but must go through its regular course, have its proper time to harden between each coat and process; and the rubbing down must be patiently and gently done—heavy pressure will only defeat the end in view. Great care should be taken in the selection of the pumice-stone, both lump and ground, as the slightest particle of grit or hard pressure will scratch, and thus cause hours of labor to be thrown away.

In describing the material used for the purpose, we shall only describe that which we consider best suited for getting up the white or light-tinted enamel. There are several kinds of filling up color used and sold by the colorman, but most of them are of a dark color, not suited for light work, as they require so many coats of paint afterwards, to get a pure body of color, that it defeats its own object. In practice, we find it best to fill up from the first with the same tint of color we intend to finish with, thus forming a solid body of pure color, which will bear much rubbing down without being shady. For all dark grounds, which have to be finished a dark color, the black or dark filling is the best.

The tools and material required are as follows, viz:

1. White lead ground in turpentine, and best white lead in oil.
2. A clear, quick, and hard-drying varnish, such as best copal, Manders Brothers' white coburg, and white enamel varnish, etc., etc.
3. Ground and lump pumice-stone, or putty powder.
4. Rotten stone, ground in water or oil.
5. Some white felt, from a quarter to half an inch in thickness, and of the best quality.
6. Several flat wooden blocks, of various sizes and forms, suitable for getting into corners and mouldings; these must be covered with the felt on the side you intend to use.
7. Two or three bosses made with cotton wool, and covered with silk.
8. Sponge, and wash or chamois leather.

In order to simplify the description, we will take a plain panel to operate upon. If it is new, give it two coats of oil color, mixed in the ordinary way; now mix the white lead, ground in turps, with only a sufficient quantity of varnish to bind it with, thinning to a proper consistency with turps. It is as well to add a little of the ordinary white lead, ground in oil, as it helps to prevent cracking. Give the panel four or five coats of this mixture, leaving a sufficient interval between each coat to allow it to dry well. Let it stand for a few days, until it is hard enough to rub down. When it is ready, you may rub it down, first with a soft piece of lump pumice-stone and water, to take off the rough parts. Now use the felt and ground pumice-stone, and cut it down, working the hand in a circular form or manner. You will require to exercise much care and patience to rub it down to a level surface, and without scratches. When you have got it down level, if it is scratched or not sufficiently filled up, give it one or two more coats, laying it on as smoothly as you can, and rub down as before. If done properly, it will now be perfectly smooth, level, and free from scratches; wash well down, and be careful to clean off all grit or loose pumice-stone. Now mix flake white from the tube with the before-named varnish, till it is of the consistency of cream. Give one coat of this; when dry, give another, adding more varnish to it. Now, let this dry hard, the time for which will of course depend upon the drying qualities of the varnish; some will polish in eight or nine days, but it is much the best to let it stand as long as you possibly can, as the harder it is the brighter and more enduring will be the polish. When it is sufficiently hard, use the felt and very finely ground pumice-stone and water; with this cut down until you get it perfectly smooth; now let it stand for a couple of days to harden the surface, then take rotten stone, either in oil or water, use this with the felt for a little while, then put some upon the surface of the silk boss, and gently rub the panel with it, renewing the rotten stone as required. It is always better to rub in a circle than straight up and down, or across. Continue this until you have got it to a fine equal surface all over; it will begin to polish as you go on, but it will be a dull sort of polish. Clean off—if the rotten stone is in oil, clean off with dry flour; if in water, wash off with sponge and leather, taking care that you wash it perfectly clean, and do not scratch. You will now, after having washed your hands perfectly clean, use a clean damp chamois leather, holding it in the left hand, using the right to polish with, keeping it clean by frequently drawing it over the damp leather. Now use the ball of the right hand, press gently upon the panel, and draw your hand forward or towards you; if you do this properly, it will bring up a bright polish on the work, and every time you bring your hand forward a sharp shrill sound or whistle will be produced—if this is the case, you may be sure you are in the right path. Continue this until the whole surface is of one even bright polish. It will be some time, and will require much practice, before you will be able to do this in the best manner; but with perseverance and practice the difficulty will soon vanish. A soft smooth skin is best for polishing; if it is dry and hard it is apt to scratch. The latter part of these instructions referring to the polishing, will, of course, apply to polishing upon imitation woods and marbles, or on any polishing varnish, using the varnish pure, of course.

HEATING CARS BY STEAM.

Translated from "Polyt. Centralblatt."

Practical experiments on a large scale have been made in Germany on this subject, especially by the Brunswick Government R. R., the Prussian Eastern R. R., the Hanoverian Government R. R., and the Lower Silesian R. R.

On the Brunswick R. R. the steam was taken from the boiler of the locomotive, passing through a small cock of $1\frac{1}{4}$ in. interior diameter, into a large pipe of copper about 20 in. in diameter. Two such copper pipes were laid lengthwise below the floor of each passenger car, and connected by hose with the pipes of the adjacent cars. The pipes were covered by a grate along the walking floor. Under the seats they were covered by a wide box of sheet iron open in front so as to let the heat into the compartment and to protect the seats from the immediate radiation. These arrangements effected an increase of temperature in the cars of about 25° F., which is quite a favorable result.

On the Prussian Eastern R. R. the heating by steam of the passenger and baggage cars of the express trains was introduced in January, 1865. The steam is produced by a small tubular boiler standing in a compartment of the baggage car, and is carried along the train through a $1\frac{1}{4}$ in. pipe fixed to the lower part of the wagons. The maximum steam pressure is 30 lb. The pipes are joined by caoutchouc hose between the wagons. The heating of the compartments is effected by hollow cylinders connected below with the above described main pipe. The admission of the steam into the cylinders is regulated by cocks or valves from the outside of the wagons. It has not been found convenient to have this regulation done by the passengers from the inside of the compartments, and all the arrangements put in at first for this purpose had to be removed. The temperature in the wagons can easily be increased 50° F.

The steam pressure is very nearly the same over three wagon lengths, and consequently the heating power of the cylinders is about equal in the first three wagons. The above arrangements would therefore be sufficient for a larger number. No objections nor difficulties of any importance have been met with in using this system. The trains are running regularly over a distance of several hundred miles. The consumption of coal is about $1\frac{1}{2}$ lb. per English mile, thus causing but a very small expense.

The Hanoverian Government R. R. runs daily two mail trains, with steam heating, between Cologne and Berlin. The steam is generated in a small tubular boiler put up in a compartment of the baggage car. The heating pipes are laid through the cars lengthwise, their axis being about at the level of the floor. The wagons of one train contain four parallel pipes of wrought iron, those of the other train contain but two pipes of sheet iron. Both kinds of pipes have a diameter of $2\frac{7}{8}$ in. They are situated at a height of but one inch between the passenger seats, and located there immediately below the floor, so that a thin sheet of iron with which they are covered is even with the floor level. The emanation of the heat takes place principally below the seats, where the pipes are uncovered. This emanation can be lessened and regulated by valves so arranged as to cover the pipes more or less. The valves can be worked from the outside of the cars by the employees, as well as from the inside by the passengers. On the first trial of these heating arrangements the temperature of the air was raised from 41° to about 60° F. The consumption of coal amounted to 25 lb. per hour, during which time 175 lb. of water were used. The whole arrangement has been found good and convenient. Further experience will show if it will prove sufficiently effective in severe frost.

The steam heating machinery actually in course of construction on the Lower Silesian railroad is similar in principle to that of the Hanoverian railroad. The details are not yet known. S.

IRON AND STEEL NOTES.

Silicon and Sulphur in Cast Iron.—The following practical remarks, on the making of pig iron, are culled by the "American Exchange and Review," chiefly from the new edition of Kerl's Metallurgy, by Dr. Crookes:

When casting pig iron in cast-iron moulds (chills), it will be found that the least silicon is contained in the lower part of the pig, on the other hand most of the combined carbon; whilst the upper part of the pig is richer in silicon and other substances which may separate. In such cases most of the manganese will also be found in the upper part. Upon casting pig iron in moist sand, the lower part of the pig is less modified. It is therefore advisable to cast good forge pigs in cast-iron moulds forming thin plates.

The following plans may be adopted for producing pig iron poor in silicon: Employing low temperatures and carbonizing the iron as perfectly as possible; or if a higher temperature is required, employing admixtures of lime to render basic the sufficiently aluminous mixtures from which silicon is reduced with more difficulty than from silicious mixtures poor in alumina; and, finally, adding manganiferous fluxes. The latter fluxes partly render the mixture easier to fuse, and the manganese combines with the silicon and separates on the surface of the liquid iron. According to Lohage, manganese, as well as aluminium, also facilitates the separation of silicon at the smelting of cast steel.

Good gray foundry pig iron may contain as much as two per cent of silicon; if containing a larger amount, it is harder and less strong, but it may be improved by remelting, when part of the silicon will be separated. Such iron, containing an excess of silicon, is fine grained, of light color, has but little lustre, and solidifies quickly.

Forge pig iron suffers more loss by scorification the more silicon it contains; it may, nevertheless, be more advantageous to produce pig iron rich in silicon and poor in sulphur, when treating impure ores at a high temperature, than by employing a low temperature to produce iron poorer in silicon and richer in sulphur, as silicon may be more perfectly separated than sulphur. The state of combination of the silicon essentially influences the behavior of the iron at its conversion into malleable iron.

Lohage suggests that gray forge iron should contain at least two per cent of silicon in order to form a slag which shall thus preserve the iron from further oxidation; and as the silicon first oxidizes, time is allowed for the separation of sulphur and phosphorus. Forge iron containing about 1.5 per cent of silicon is not usually desirable.

The higher sulphides lose in the upper parts of the furnace part of their sulphur, with iron, if iron is present in a reduced state, and if the temperature is sufficiently high. The sulphur in pig iron does not seem to be always combined with iron, but sometimes with silicon. Schafhäutl mentions an instance, that at the tapping of pig iron in the Tividale iron works, near Dudley, sulphide of silicon, of the composition Si^2S^3, analogous to the oxide of silicon, was separated in the form of a whitish-yellow, spongy, earthy substance. The sulphur is frequently not divided uniformly in the pig iron, and in the common pigs collects more in the upper part than in the lower part.

Additions of lime whilst applying higher temperatures, thus forming sulphide of calcium, which has the property of dissolving other metallic sulphides (sulphides of iron, manganese, etc.), and of sending them into the slag. This re-agent is more effective if the sulphur is contained less in the ore than in the gangue, fuel and fluxes, as, in the latter case, sulphide of iron is not at first formed, but sulphide of calcium, which directly enters the slag. Slags produced at Hattingen, from iron pyrites of the coal measures, contained from four to six and a half per cent of sulphide of calcium.

The Chemistry of the Blast Furnace.—The following are the principal points in the recent paper of Mr. I. Lowthian Bell, read before the Chemical Society:

Scheerer, Tunner and Ebelman, who have made experiments on the subject, have laid down with apparent precision the parts of the furnace, and the temperatures at which the different stages of the manufacture of iron—the reduction of the oxide and the union of the iron with carbon—take place. The former is commonly supposed to happen at a very considerable temperature, while the latter is commonly believed to take place in the hottest part of the furnace. Mr. Bell has arrived at conclusions altogether different. His results go to prove that the deoxidation of the ore takes place at a comparatively low temperature, and that the carburization is effected long before the metal is liquified and separated from the slag.

Mr. Bell dissents from Scheerer's representation of the various changes that go on in the blast-furnace, as taking place in zones; and he seems to attach much more significance to the term used by Scheerer than need be. The "Mining Journal" says: We are disposed to consider that the zones spoken of by Scheerer, where the reduction, carburation and fusion of the metal take place, are so far real that they are at least relatively different parts of the blast furnace, not, indeed, definable by absolute lines, but still in a certain degree distinct. That in certain furnaces the zone of reduction should tend to assume the form of an acute cone, rather than a layer with horizontal boundaries, is quite conceivable; but whatever be the configuration of its vertical or horizontal areas, it is not the less distinct and different from the zones of fusion, carburation and calcination, where processes of a different nature are in progress.

The attainable economy of fuel in smelting iron is another point to which Mr. Bell directed attention. When it is considered that something like two and one-half tons of coal are consumed in producing one ton of pig iron, even when hot blast is used; and that to effect the chemical change of smelting, only eight hundred weight of coal are needed, still leaving one-half of the heating power of that coal unapplied, and available for further use, the great importance of devising means of economizing fuel in this operation will be obvious. More than four-fifths of the coal consumed in producing pig iron, is consumed in raising the temperature of the charge to effect fusion, and that is done under the most disadvantageous circumstances as regards production of heat.

The gases escaping from the throat of a blast furnace have not only a large amount of unused heat-generating power, but they have also a temperature and reducing power capable of preparing ore for the subsequent processes of the blast furnace. In the Cleveland district economy in this direction has been carried to a considerable extent, by increasing the height of the furnace, and thus taking off the gas at a lower temperature than is sometimes the case elsewhere. But it is from the higher heating of the blast that greater economy is now to be looked for. The idea that hot blast deteriorates the quality of iron is now pretty well exploded, and there is no reason that some advance should not be made in effecting economy of fuel by this means.

Accurate Rolling-Mill Machinery.—At length the managers of our finished ironworks are arriving at the just conclusion that most of the stoppages by the breakdown of machinery result from inaccurate adjustment and rude construction. Consequently gearing of absolute accuracy, and of greater strength with less material, is now in demand, and the works where these are produced are busy in that especial department. There can be no doubt whatever that a vast economy will result from the use of such castings, even as there is much saving yet to be effected in the engine department of our mills and forges. So soon as the iron trade generally shall see that it is not economy, but, on the contrary, extravagance, to cast their wheel gearing at home upon the old models, and shall go to our best machinists for what they require, and pay a very much larger sum for it, weight per weight, then we shall have less cumbersome apparatus, worked by engines which do not consume four times as much steam as with different gearing would be necessary. The losses which have resulted in the past year from stoppages by the breaking down of the unwieldly machinery too frequently to be observed thundering in our ironworks. are, to our knowledge in certain cases, somewhat startling. They are the more so because at neighboring works, where a heavier first cost was not shunned, and where, as a consequence, light, easy and almost silent working machinery is in operation, the stoppages have been of an insignificant character.

The foregoing is from the correspondence of "The Engineer." The same lesson has been learned by our progressive iron workers in America—and the result is the establishment of special manufactories of rolling mill machinery, such as that of Matthews & Moore, in Philadelphia, where trains of rolls are fitted up with the accuracy and solidity that characterize marine engines.

The Radcliffe Process.—An invention has recently been patented in England, by which it is claimed that masses of iron or steel may be produced of sufficient size to form girder, rail, shaft, armor plate, &c., which will be homogeneous throughout, in so far that they will be without any weld, in the ordinary sense of the term. Some years since, the welding of two or more puddled balls into one, under a steam hammer, was practised in Wales, and more recently in America, for instance at the Albany Iron Works; and by this means large masses were produced, but the process was not satisfactory, because the surfaces of the balls became oxidized, and good union could not always be secured between them in consequence. In the Radcliffe process, a number of puddled balls are worked together under a heavy steam hammer; but in the process here alluded to the puddled balls are welded together in a furnace, when the iron is surrounded by a neutral flame, and the oxidation of the iron is thus prevented. It is contended, also, that the cost of producing rails, armor plates, &c., by this process will be much less than by the ordinary methods. It is difficult to explain the arrangements connected with the furnace, without the aid of diagrams, but we may briefly state that a hydraulic anvil is made to work horizontally through an opening in one side of the furnace, and on the other a steam hammer is made to move in a similar manner. Thus mechanical appliances can be brought to bear upon the manipulation of a large or small quantity of iron. By an arrangement of rolls in front of the furnace, it is proposed to roll the iron into shape without reheating. The use of the hammer entering the furnace, to perform the welding in a neutral flame, was long since patented in America, by Alonzo Hitchcock, of New York.

Improvement in Iron Castings.—Messrs. Munro and Adamson, of Glasgow, have patented some improvment in the mode of manufacturing articles now made of malleable or wrought-iron, steel, or cast-iron from re-melted pigs, foundry scraps, or direct from the blast-furnace. Chills of the shape required for the articles to be produced are provided, and molten iron is run into them. As soon as solidified, and for the purpose of making the material very hard and dense, the casting may be taken from the chills and cooled in water or otherwise, or it may be allowed to remain in the chill for a longer period, or the chills may be surrounded with or cooled by water. In place of forming the chill castings of absolutely crude iron, the iron before being cast may be partly refined by blowing atmospheric air into its mass, or by placing compounds of oxygen into the vessel or furnace wherein it is refined. The chilled castings are afterwards annealed or tempered, thus producing a material possessing many of the properties of wrought, forged, or malleable iron, but avoiding the costly manufactureof iron now in use.—*Mining Journal.*

If we had not tried a part of this invention without success,we might believe it new and useful.—Ed. *V. N's Mag.*

Cryolite in iron Furnaces.—The "Colliery Guardian" contains the following paragraph:

"An invention patented by Messrs. James Bowron and George Lunge, of England, consists of mixing fluoride of calcium, the same being obtained artificially or in the form of a native fluor spar, or the mineral known as "cryolite," either in a state of fine division or otherwise, with the materials used in blast furnaces, for the purpose of removing, wholly, or in part, the phosphorus contained in the pig iron to be obtained therefrom. The invention further consists in using fluoride of calcium in puddling and other furnaces, to aid in the manufacture of wrought-iron and steel by the removal of the phosphorus contained therein. The phosphates resulting from such treatment may be utilized as manure."

We hear that the "Stevens Flux," notorious in this country for its brave promises and halting performances in the extraction of "more gold than could be found by ordinary assay," has already found a sphere of real usefulness in the metallurgy of iron—though we are not prepared to say that its application is novel or that its employment at the price charged for it will prove economical. As we have often said, whatever good qualities the Stevens Flux possesses are probably shared by native fluor spar; and now, for the consolation of Col. Stevens, we will reverse the case, and say that whatever advantages the above patent of Bowron and Lunge presents, are probably shared by his Flux. What's sauce for the goose is sauce for the gander.—*American Journal of Mining.*

Coating Iron with Brass.—A new process has just been patented of coating iron with brass, copper, silver and other metals, which bids fair to work almost a revolution in some of the trades of Birmingham. One method heretofore employed is veneering—if that term be applicable to metal—but the expense and difficulty attending it have been an objection to it from the first. Electro-plating by various processes has been attended with much greater success, but even this coating is not so durable as could be desired. What has long been wanted is a method of coating iron with brass or silver, as readily as it is now coated with tin, and so as to render it equally durable. This has been at length successfully accomplished by a Wolverhampton patentee with remarkable success. The process adopted is that of immersion, but of course the details of the invention are for the present kept secret. I have seen, says the correspondent of "The Engineer," some sheets of iron which have been coated with copper on this principle, quite equal, for all practical purposes, to sheets of copper. They will bear stamping into all imaginable shapes, and even burnishing, without removing the copper coat, the latter having to all appearance eaten its way into the inferior metal. Coated iron on this principle will supersede brass and copper to an enormous extent, for while it will be equally serviceable, it will be 40 per cent lower in price.

The Durometer.—An instrument for testing the hardness of metals, by drilling, has been invented, says the "Builder," by M Behrens, an engineer of Tarbes. in France. It is said that it has been thoroughly tried, and that many French contracts for rails now contain a condition that they are to be tested by this apparatus. It consists of an upright cast iron standard bolted down upon a bedplate, and provided with a table for supporting the rail or other article to be tested. The spindle of the drilling tool is capable of being raised and lowered in its bearings by turning a handle for that purpose, and the drill is held down to its mark by a weight fitted to the upper end of the drilling spindle. Its rotary motion is derived, through a pair of mitre wheels, from a driving shaft carrying the usual fast and loose pulleys. This shaft has a worm upon it which moves a train of mechanism, in connection with a signal gong, for the purpose of indicating the number of revolutions made by the drill. The apparatus is exceedingly compact. Its use by French manufacturers has led to a gradual increase in the hardness of the rails they produce.

Estimating the Impurities in Iron.—Gintl gives a very easy method of determining the impurities in cast iron. It is applied by him to the estimation of the sulphur contained in the iron, but, as will be seen, it is available for the separation and determination of most of the usual impurities. The iron is reduced to as minute a state of division as possible, and is then treated with a strong solution of perchloride of iron, as nearly neutral as possible. The mixture is kept heated for ten or twelve hours, at the end of which time almost all the iron will be found to have dissolved, leaving, as a residue, the carbon, sulphur, phosphorus and silicium, together with the little iron left undissolved. This residue has only to be well washed, oxidized and dissolved, and the sulphur estimated as sulphate of baryta. The exact plan directed by the author is to introduce the residue and filter into a porcelain crucible, having, at the bottom, three parts of nitrate of potash and one part of hydrate of potash; heat to fusion, dissolve and precipitate with chloride of barium. The phosphorus and silica will be contained in the same solution, and can be determined separately. —*Mechanics' Magazine.*

A New Fact in the Behaviour of Iron.—Mr. Gore has noticed a new fact in the behaviour of iron under the influence of heat and of strain. A strained iron wire was heated to rednesss by a current of voltaic electricity, and then, the current being discontinued, was allowed to cool. It was observed that there arrived a moment in the process of cooling at which the wire suddenly elongated, and then gradually shortened, until it became perfectly cold, remaining, however, permanently elongated. No other metal besides iron exhibited this peculiarity, which Mr Gore attributes to a momentary molecular change, and he points out that this change would probably happen in large masses of wrought-iron, and would come into operation in various cases where those matters are subjected to the conjoint influence of heat and strain, as in various engineering operations, the destructions of buildings by fire, and other cases. The phenomenon deserves a further investigation, since every fact relating to iron is of importance to us.—*Mechanic's Magazine.*

Effect of Phosphorus on Iron and Steel.—With respect to the influence of phosphorus and slag in iron, Professor Styffe has a theory that the diffusion of slag through iron containing phosphorus, has a beneficial influence in counteracting the injurious effect of the phosphorus. The results of experiments as to the influence of this material upon the tenacity of iron, agree pretty closely with those of Karsten and others. The author says: "The tensile strength of iron is not sensibly impaired by the presence even of 0.2 or 0.3 per cent of phosphorus, provided the metal has not been strongly heated after having undergone the operation of rolling or extension by other manipulation." He even maintains that the presence of even a considerable quantity of slag or cinder in iron impregnated with phosphorus is beneficial, by preventing the largely crystalline structure which would otherwise result from the presence of that element. With respect to the influence of phosphorus in steel, the author, on the contrary, confirms the opinion that it is injurious, rather than beneficial, and says that he knows no authenticated instance in which the proportion of phosphorus has been higher than 0.4 per cent in what has been considered as good steel.

Tungsten Steel.—It is many years since Mr. Mushet proposed to alloy iron with tungsten in the formation of steel. We reported a year or two ago that Mr. Leguen, in France, had made experiments with the same alloy, employing iron converted by Bessemer's process. Then he used a common gray pig, not fit for conversion, but produced, nevertheless, an alloy of very good quality. Lately, he has continued his experiments, now employing good white cast iron, and has produced a steel of excellent quality. A portion of the iron is first alloyed with one-tenth wolfram, in a cupola furnace, and is added to the rest in the converter. The conversion is carried further than usual, so that the carbon is reduced to one-half the ordinary proportion. The steel so produced is soft, but very tough, and tempers remarkably well. Mr. Leguen mentions that it will be found extremely useful for machines, some parts of which require to be tempered, while others are kept soft. The objection brought against this alloy is that it is expensive, but the amount of tungsten employed by Mr. Leguen is so small—only 0.55 per cent—that it can make but a very small addition to the cost of the steel.—*Mechanic's Magazine.*

Testing Boiler-plates by the Saxby Method.—During the past year the Saxby method of detecting flaws in iron, by the deflection of a magnetic needle, has been experimented with in England with especial reference to the detection of flaws in boiler-plates. In one of these trials a piece of partly used plate, that had successfully withstood all the Admiralty tests, was shown by the new method to possess a weak point; the existence of the defect and the efficacy of the method being subsequently proved by a re-examination of the plate by mechanical means. So successful have been the trials thus far made, that Mr. Saxby is led to claim for his method the attribute of infallibility.—*American Artizan.*

To renovate old Files and Rasps.—A file or rasp worn smooth is immersed for a time in a mixture of one part nitric acid, three parts oil of vitriol and seven parts water. The time it must be allowed to remain in this acid bath depends upon the quality of the metal. A very hard steel will require a longer immersion than a soft fine-grained metal. The tool is then well rinsed in water, and then (to ensure the perfect removal of the acid) in milk of lime. It is afterwards to be dried, and the lime is brushed away. When new files are made by this plan, they require a little additional treatment to protect them while in stock. After they have been carefully dried, and the lime has been brushed away, they are to be brushed over with a mixture of olive oil and turpentine, and, lastly, well rubbed with very fine charcoal powder. Any one would imagine that the acid, acting equally on all parts, would simply dissolve away some of the metal, and leave the file as smooth and useless as before. But such, we are assured, is not the case. Files may be renovated over and over again, and are always as good as new.—*Mechanic's Magazine.*

Casting a 70-Ton Anvil Block.—At the new Steelworks at Landon recently, a 70-ton block for a steam hammer, was successfully cast by Mr. Williams of St. Helen's Works Swansea. Two cupolas were specially erected at a suitable distance to enable the metal to run directly into the mould. Operations commenced at an early hour, and by a quarter to 10 a. m. the charges began to follow each other at regular intervals at three-quarters of an hour up to 9 p. m., at which time the block containing seventy tons of iron was finished. This is the largest casting ever made in Wales. The dimensions are 11 ft. 6 in. by 9 ft. 6 in. at base, and 7 ft. 6 in. high, and it will occupy from two to three weeks to cool sufficiently to allow it to be reversed, it having been cast base uppermost. Trunions joining part of the casting are so placed that it will simply be turned upon its own axes.

The Siemens-Martin Process in France.—The Terrenoire Ironworks have now four Martin furnaces in operation. Ere now this process has been carried on, introducing scraps of Bessemer steel into cast iron. It is necessary, of course, that this cast iron be entirely free from phosphorus. Some trials have been made in the use of worn out rails instead of Bessemer steel, but that has been a complete failure. The rails were exceedingly brittle, and the railway companies have forbidden the mixture of old iron rails with the Bessemer steel used in the Martin process. This difficulty might be avoided with good iron obtained from a cast iron free from phosphorus, but the price of the steel would be greatly increased. This process will be very useful to the makers of Bessemer steel, enabling them to get rid of their scrap.—*Correspondence of The Engineer.*

RAILWAY NOTES.

Freight Cars with Changeable Gauge.—A new through freight line between Boston and Chicago, called the "National Despatch Line," are now running a through line of changeable gauge of freight cars, between those cities, passing over the Boston and Lowell and Nashua, Concord, Northern (N. H.), Vermont Central, Montreal and Vermont Junction, Grand Trunk and Michigan Central Railways, comprising the 4 ft., $8\frac{1}{2}$ in., and 5 ft. 6 in. gauges. One hundred of those cars are now in use on the line; a part of which have been running since the 1st of January very successfully and satisfactorily, and it is intended immediately to increase the number of cars to five hundred, and afterwards to further increase the stock as the business requires.

ENGLISH LOCOMOTIVE EXPENSES.

COMPARATIVE STATEMENT OF HALF-YEARLY MILEAGE, LOCOMOTIVE EXPENDITURE, AND TRAFFIC RECEIPTS OF VARIOUS ENGLISH LINES.

Half-year ending January, 1869.

NOTE.—We gave last month a table showing the total expenses of the principal British lines. The following table, from "Engineering," gives the details of locomotive expenses on some of these lines.

Four Coupled Express Engine—Paris and Lyons Railway.—This type of engine may thus be generally described: Outside horizontal cylinder 17.33 in. in diameter by 25.6 in. stroke, four driving wheels 6 ft. 6.2 in. in diameter and 6 ft. 10 in. apart, and a pair of leading wheels 3 ft. 11.66 in. in diameter and 6 ft. 2.4 in. forward of front drivers. The driving wheels have only two springs, the axles being connected by compensating beams. The following particulars (and also engravings) appear in "The Engineer" of May 21, 1869:

	ft.	in.
Length fire grate	4	4
Width do	3	$3\frac{1}{2}$
Surface of grate in square feet	15	0
Height inside copper fire-box near the tubes	5	3
Height near the door	4	$10\frac{1}{2}$
Length at the top	4	2
Length at the bottom	4	4
Width	3	$3\frac{1}{2}$
Thickness of side plate	0	$0\frac{1}{2}$
Thickness of door plate	0	$3\frac{3}{5}$
Thickness of copper tube plate at the top	0	1
Thickness of copper tube plate at the bottom	0	$0\frac{1}{2}$
Number tubes	164	
Outside diameter	0	2
Thickness	0	$0\frac{1}{12}$
Length between plates	16	$3\frac{1}{2}$
Length outside fire-box	4	11
Width at the top	4	$2\frac{1}{5}$
Width at the bottom	3	$10\frac{1}{5}$
Thickness	0	$0\frac{1}{2}$
Outside diameter small plates of shell,	4	$1\frac{1}{5}$
Length of shell	16	$0\frac{2}{5}$
Height of the centre above the rails	6	$4\frac{1}{2}$
Steam pressure	120 lb.	
Diameter of each of the two safety valves	0	$4\frac{2}{5}$
Heating surface fire-box, square feet	80	
do tubes, square feet	1260	
do total	1340	
Inside diameter chimney	1	$4\frac{1}{2}$
Height above the rail	14	4
Transverse distance frames	4	$0\frac{2}{5}$
Thickness do	0	1
Total length of the engine	29	$7\frac{3}{5}$
Diameter of leading wheels	3	$11\frac{2}{3}$
Diameter of driving and trailing wheels	6	$6\frac{1}{5}$
Distance from leading to driving wheels	6	$2\frac{2}{5}$
Distance from driving to trailing wheels	6	10
Total wheel base	13	$0\frac{2}{5}$
Transverse distance between wheels	4	$5\frac{1}{2}$
Transverse distance between centers of journals	3	$8\frac{1}{3}$
Length of journals of leading wheels	0	$9\frac{5}{6}$
Diameter of do do do	0	$6\frac{1}{3}$
Length of journals of driving and trailing wheels	0	$9\frac{5}{6}$
Diameter of journals of driving and trailing wheels	0	$7\frac{1}{3}$
Number of plates in springs of driving wheels	16	
Thickness	0	$0\frac{3}{5}$
Width	0	$3\frac{1}{2}$
Length driving spring plates	3	9
Number of plates in springs of leading wheels	11	
Thickness	0	$0\frac{1}{2}$
Width	0	$3\frac{1}{2}$
Length	2	10
Camber	0	$3\frac{1}{6}$
Diameter of cylinders	1	$5\frac{1}{3}$
Stroke	2	$1\frac{3}{5}$
Length of connecting rod	5	11
Transverse distance between centers of cylinders	6	$2\frac{4}{5}$
Angle of advance of eccentrics	30 deg.	
Throw of eccentrics	0	$2\frac{2}{5}$
Stroke of slide valves in full gear	0	$4\frac{2}{3}$
Inside lap of slide valves	0	$0\frac{1}{50}$
Outside lap of slide valves	0	$1\frac{1}{5}$
Length of steam ports	0	$11\frac{4}{5}$
Width of steam ports	0	$1\frac{2}{5}$
Width of exhaust ports	0	$2\frac{3}{5}$
Weight of empty engine	30 tons 8 cwt.	
Length of connecting rod	8	$4\frac{2}{3}$
Diameter of connecting rod	0	$4\frac{2}{3}$
Length of coupling rod on driving wheels	0	$3\frac{1}{2}$
Diameter of coupling rod on driving wheels	0	$4\frac{1}{3}$
Length of coupling rod on trailing wheels	0	$3\frac{1}{2}$
Diameter of coupling rod on trailing wheels	0	$3\frac{1}{2}$

Distribution of Weight in Working Order.

	tons.	cwt.
Leading wheels	9	9
Driving wheels	12	11
Trailing wheels	12	5
Total	34	

These engines run at an average speed of forty-five miles an hour, traversing inclines of 1 in 200 with trains weighing 115 tons, exclusive of the tender, which weighs twenty-three tons in working order. They are very steady, and the company have been so well satisfied with their working, that after a first supply of fifteen engines, fifteen more have been ordered.

The Railroads of the United States.—From a comprehensive abstract in the New York "Times," of Mr. Henry V. Poor's new work on Railroads, we compile the following statistics: There were in operation in all the States, on the 1st day of January, 1869, 42,255 miles of line, the cost of which, at $44,000 per mile, equaled $1,800,000,000. The total amount of net tonnage transported over them for the year equaled 75,000,000 tons, having a value of $10,472,250,000—a sum equaling six times their cost, and more than four times greater than the whole amount of the national debt!

The construction of these works upon a grand scale commenced with the discovery of gold in California, in 1848. The number of miles in operation in the country, on the 1st day of January of that year, was 5,599. The mileage annually constructed from the opening of the first section (23 miles) of the Baltimore and Ohio Railroad in 1830, to 1847 inclusive, equaled 311 miles. The yearly average opened from 1848 to 1860, inclusive, equaled 1,925 miles—the aggregate opened in this period being 25,037 miles. During the war the number of miles built equaled 3,273, or 818 miles annually. Since 1864, 8,347 miles have been opened, or 2,086 miles annually. The number of miles opened the past year equaled 2,979 miles.

There are in progress fully 15,000 miles of line, of which at least 5,000 miles will be opened the present year.

The ratio of mileage of these works to our total population is as 1 of the former to 876 of the latter. The ration in the New England States is as 1 to 846 ; in the Middle, 1 to 1,037; in the Southern, 1 to 969; and in the Western, 1 to 731. The State of New Hampshire has 1 mile of railroad to 500 inhabitauts; the State of Nebraska, 1 to 163; and the State of Florida, 1 to 343.

The State having the largest proportionate mileage is Massachusetts, which has 1 mile of road to 5.47 square miles of area. The State of Ohio has 1 mile of line to 11.76 square miles. A ratio similar to that for Massachusetts would give to the whole country 600,000 miles of line. One similar to that for Ohio, 300,000 miles. The total amount of net tonnage transported over all the railroads of the United States for the year 1851, did not exceed 5,500,000 tons. The rate of increase from that year to the close of 1867, in which year 75,000,000 of tons were transported, exceeded 1,300 per cent. The tonnage traffic of all the roads in the country in 1858 equaled 18,750,000 tons. The increase in the decade commencing with this year consequently equaled 300 per cent traffic.

The value of the tonnage for 1867 is estimated to equal that of the several classes of freight transported on the Erie canal for that year, (the value o. which is carefully ascertained,) or $139.63 per tonf The aggregate value of the tonnage of all the roads equaled, consequently, the enormous sum of $10,472,250,000. At a similar estimate the value of the tonnage transported in 1851 equaled $765,236,725; in 1858, $3,096,762,500. The total increase in value of the tonnage transported in 1867 over that transported in 1851 equaled $9,707,013,275, and $7,375,487,500 over that transported in 1858.

Our railroads transport, on an average, 2,000 tons to the mile. The tonnage of the railroads of Massachusetts, for 1867, equaled 5,394,137 tons, or 3,853 tons to the mile. That of the railroads of New York equaled 10,343,681 tons, or 3,501 tons to the mile ; that of the railroads of Pennsylvania equaled 35,383,370 tons, or 7,864 tons to the mile. The tonnage borne on the railroads of those States having a mileage of 8,750 miles equaled 51,121,140 tons, or 5,826 to the mile. The tounage of most of the great roads far exceeded the estimate. The aggregate amount transported could not have been less than 100,000,000 tons.

Over ordinary highways wheat will bear transportation only 250 miles; Indian corn only 125 miles. Upon railroads these, the most valuable of our cereals, will bear transportation 3,200 and 1,600 miles, respectively. The area of a circle drawn upon a radius of 125 miles equals 49,077 square miles; that of a circle drawn upon a radius of 1,600 miles, 8,042,496 square miles.

The total earnings of all the roads in the United States in 1851 equaled $39,406,358. The receipts from freight and passengers were almost exactly balanced. The earnings from all sources in 1867 were $400,000,000, of which $280,000,000 were received from freight, and $120,000,000 from passengers. The rapid increase of earnings from freight is a most favorable feature. The earnings of the English railways in 1851 were $73,000,000, of which $35,000,000 were from freight, and $38,000,000 were from passengers. In 1867 their total earnings were $190,000,000, of which $105,000,000 were from freight, and $85,000,000 from passengers. The ratio, in this country, of earnings from freight to earnings from passengers is as 2.2 to 1; in England is a little over 1.1 to 1.

The earnings of American roads are more than twice greater than those of England. The railroad mileage of that country in 1867 was 14,247; in the United States, 39,276. The cost of the former, equaled very nearly $2,500,000,000, that of the railroads of the United States, for the same year, $1,700,000,000. The earnings of the English roads, upon their cost, equaled 7.86 per cent ; those of the United States very nearly 25 per cent. The English roads, however, have a great advantage over our own in operating expenses, their net earnings, as a rule, fully equaling one-half of the gross receipts. In this country the net cannot be estimated at over 30 per cent of the receipts. The following statement presents in detail the various items entering into the cost of operating the railways of the two countries—the railroads of the State of New York being taken as representing those of our own :

Items of cost per train, mileage of running trains upon the railroads of New York and Great Britain for 1867 *:*

	New York. Cents.	Gt.Britain. Cents.
Maintenance of way, including iron	49.50	12.70
Repairs of engines and materials	17.35	6 45
Repairs of cars	21.18	6.74
Wages of engineers and firemen	8.36	3.00
Fuel	21.60	3.42
Local taxes	5.50	2.20
All other charges	42.62	26.86
Total	166.00	61.37

The preceding statement shows the cost per mile of operating the railroads of the State of New York to be two and a half times greater than that of operating the railways of Great Britain. The earnings of our roads, however, per mile run are nearly twice greater—the average earnings of the former being $1 25 per mile ; of the latter about $2 30 per mile. The most startling difference in the items of cost is in the matter of fuel ; the cost of the same in this country being 21.60 per mile, in England 3.42 per mile.

In 1880 the population of the United States will equal 50,000,000. Its railroad mileage will equal 70,000 miles. At the estimate of only 2,000 tons to the mile their aggregate tonnage will equal 140,000,000 tons, having a value of more than $20,000,000,000, while our population is increasing at the rate of 1,200,000 annually.

THE NEW YORK CENTRAL Company recently paid a million of dollars for four acres of land for a terminus in New York.

Locomotives of the Paris, Sceaux and Limours Railway.—This railway has curves of 82 ft. radius. The engines have four driving wheels, but the wheels on the opposite sides are independent of each other, and are driven by two cylinders for the right and two for the left pair of wheels. The driving tyres are 12 in. wide, without flanges. The leading and trailing wheels are flanged, and are loose on the axle, (which is free to turn raidally to the curve), and they are fitted with "guiding bogies" which have wheels lying nearly horizontally and bearing against the inner edge of the rails. The following are particulars of the engines, from "Engineering," January 29, 1869, in which paper the machinery is illustrated.

	Engines with four cylinders, built in 1855, and subsequently altered.	Engines at Ivry in 1867.

Heating surface; firebox	56	80 sq. ft.
Total	800	1,314
Weight in working order:	tons.	tons.
On leading wheels	8	10.3
On front pair of coupled wheels	12	12.0
On hind pair of coupled wheels	12	12.0
On trailing wheels	8	8.7
Total weight	40	43.0
Weight available for adhesion	24	24
Capacity of water tanks	880 gallons	
Quantity of coal carried		$2\frac{1}{2}$ tons

One of the engines was subjected to some trials with a train of forty carriages. In passing round the terminal curve of 25 metres (82 ft.) radius, this train covered three-quarters of a circle; seven carriages projecting beyond the engine and half the train proceeding in the opposite direction to the latter. In another trial a train of thirty-seven carriages carrying 1,200 soldiers, run from Bourg-la-Reine to Orsay round the terminal circle at the latter place, ascended the incline of 1 in 180, and returned to the point of departure in 43 minutes.—The distance run was 28 kilometres, or about $17\frac{1}{2}$ miles, so that the average speed was about $24\frac{1}{2}$ miles per hour. The reverse curves at Palaiseau (328 ft. radius) was traversed at 25 miles per hour, and the terminal circle at Orsay at a speed of from 7 to 8 miles per hour. The total mileage run during the year is 236,000 kilometres, or 160,000 miles. The cost of maintenance of the carriage stock is 0.3 francs per kilometre, or 4.8d. per mile, and the cost for lubrication 0.18 francs per kilometre, or 2.88d. per mile. The cost of traction varies from 0.8 to 0.9 francs per kilometre, or from 12.8d. to 14.4d. per mile.

This system of locomotives and cars (similarly constructed) is that of M. Arnoux, and it has been in regular and successful operation for some fifteen years.

Steel v. "Best" Iron Rails.—In the autumn of 1867, Captain Tyler and Mr. C. W. Eborall visited the Grand Trunk Railway of Canada and reported in great detail upon its financial, structural, and mechanical condition. Upon the question of rails, Captain Tyler observed in his report:

The difficulty of obtaining durable rails of iron has of late years been very generally felt, and has induced an outcry for steel rails in quarters where it would not otherwise have been heard. Much trouble has resulted, and much expense been incurred, for the want of rails of good quality in England, and still more in the United States, and in Canada. . . . In Canada, as elsewhere, after the failure, from lamination, of steel-headed rails, it has been considered that it would be better economy in the end to lay down steel rails than to continue to use iron with such lamentable results. . . . But I have, after careful inspection and inquiry, become convinced that iron rails of appropriate form, of suitable and reasonably good quality, and of sufficient hardness in the heads, may be made to last on most parts of the main line for fifteen years, and on the average of the Grand Trunk Railway for very much more. . . . The chance of procuring new rails of superior quality lies probably in insisting on a longer term of guarantee for the rails supplied, in employing the most reliable manufacturers and in paying a price commensurate with the value of the article. No manufacturer need have any fear of prolonging the guarantee to seven or even ten years if he only furnish a suitable rail.

The practical result of Captain Tyler's recommendations is not at all, however, what was wished, and it proves that the "outcry" for steel rails, to which he refers, was more than well founded. In the company's last report the directors remark:

The directors regret that the rails sent out from this country in 1867, purchased from the best makers, are not giving satisfaction. The directors took every precaution to secure the best rails which could be made, and exacted guarantees from the makers which they are putting in force. The small quantity of steel rails sent out in 1865, although placed on a part of the line where the traffic is very heavy, show no signs of giving way.

The engineers of the company, Messrs. E. P. Hannaford and J. F. Barnard, in their report to the directors, state that,

The rails latterly re-rolled in the United States and Toronto have proved superior to new rails imported from England. This is a very important fact, as we are of opinion new rails made from ores direct from the mine should be better in every respect than rails made from old material, which, from successive re-heating and the mixture of different qualities of iron, must of necessity prove inferior to rails made from new iron properly manufactured. In former years imported English rails have stood the test of our climate with success, although of lighter section than those now laid; and we are unable to understand why English rails cannot now be made to stand, and must press upon you the urgent necessity of insisting upon the works employed to make rails for us in England turning them out better than those imported during the past two years. The complaint we now make about the quality of English imported rails is almost universal among all railway companies in the United States and Canada. The one-third of a mile of Bessemer steel rails laid in 1865, near Kingston, continue to show no failure; not one rail has been replaced, or likely to be for years, although the traffic at this place is more than ordinary. Some of the best iron rails laid at the same time and locality as the steel have had to be removed, and others, considerably worn, must come out this year. The general condition of the track and works, as compared with former years, is satisfactory, but we would again call your earnest attention to the question of the quality of imported rails, as, until we get English rails to stand, the annual cost of renewals of iron must of necessity continue heavy, and during the present year we must incur a large outlay, owing to the bad quality of most of the English rails, and their need of being replaced before they have lasted even the lowest average.—*Engineering.*

Duties on Passengers and Tonnage.—Mr. Ashbel Welch, General President of the Camden & Amboy & New Jersey Railroad Companies, states a very large case in a very few words, in Appendix G. of the late report of the said companies:

When these companies were incorporated, during the infancy and inexperience of railroad legislation, it was unfortunately provided that they should be taxed by transit duties on passengers and tonnage. This amounted to ten cents per passenger, and fifteen cents per ton between the Delaware and Raritan, and twenty-seven cents per ton, and not quite fifteen cents per passenger, between the Delaware and Jersey city. While only passengers and high-classed goods were carried by rail, this tax was not so severely felt; but when, contrary to the contemplation of the law, low-classed tonnage sought the rail route, its embarrassing and paralyzing effect was found to be greater than any one, not called upon to deal with the subject, can readily understand.

Where there is no tax on tonnage, it is the true interest of railroad companies to make a moderate profit per ton on a large tonnage. rather than a larger profit on small tonnage; for the increase of tonnage and consequent increase of intercourse increases their other business. But a tax on tonnage prohibits, or at least limits, this policy. For example: if the profit on one ton of railroad iron, between Trenton and Jersey city, is fifty cents, without transit duty, then, with the transit duty of twenty-seven cents, it becomes twenty-three cents net to the companies. But if, by reduction of rates, the quantity is increased tenfold, as in this case is probable (the cost in consequence being also reduced), and if the profit is then twenty-five cents per ton, without transit duty, the aggregate profit is $2.50, or five times as much as on the one ton; but, with the transit duty of twenty-seven cents per ton, there ensues a net loss of twenty cents on the ten tons.—So such a reduction, as is highly advantageous, without the transit duty, would be impossible with it. The transit duties on tonnage were, therefore, sometimes prohibitory—always restrictive in their operation—and cheap transportation was impossible. The odium of this fell mainly on the companies.—They were taxed excessively by an unexpected operation of the law, and punished by the public for being so taxed.

Efforts, heretofore made to cure the evil, have failed. Public men have feared to touch the subject, as the action required might endanger the revenues of the State. At last the companies appealed to the people, and found them in advance of their representatives. It was not supposed possible to do more at first than to modify the transit duties on the lower grades of property. But with the unexpected support, and even pressure, of the people, and under the enlightened advice of the chief magistrate of the State, the Legislature wisely abolished all transit duties, and substituted other taxation.

The new law, in effect, commutes the annual State taxation of the companies at that of 1868, which was not quite $300,000. The annual increase of transit duties paid the State for the last eight years has been between $15,000 and $16,000. The new connections of the companies' works, with the roads leading south and west, the pressure upon them of cheap property, at low freights, the diversion (consequent on the consolidation of the companies' interest) of traffic to the Jersey city route, where the taxation was highest, tend greatly to accelerate the rate of increase of transit duty that would have been paid, in addition to the acceleration due to the general increase and returning prosperity of the country. Large as the fixed amount to be paid is, it is much smaller than the transit duty would have become in a very short time.

But the greatest advantage of this change of taxation is, that it gives the companies the free use of their own works—removes the dam which has so much obstructed their traffic—allows them to increase their business without paying enormously for the privilege. The excessive disparity heretofore existing between the taxation of these companies and that of other railroad companies in the State, though not removed by this law, is prevented from increasing. The greatest burden was not the amount actually paid, but the amount that would have been paid if the roads had been worked to the best advantage.

Borsig's Express Locomotives—These engines are used for what is termed "fast" passenger traffic on the Rhenish railway. They have four coupled wheels 5 ft. 6 in. in diameter. The leading wheels are 3 ft. 4 in. in diameter, and the total wheel base is 13 ft. 6 in., the distance between the centers of the coupled axles being 8 ft. 2 in. The trailing axle is placed below the firebox, the firegrate being inclined; and the driving and trailing springs are connected by compensating beams. The front ends of the two leading springs are also connected by a transverse compensating beam, which oscillates on a center below the front end of the boiler; and it follows from this arrangement that the engine is virtually carried on three points. All Borsig's engines are supported on the springs in this way, and the same or equivalent arrangements are adopted on almost all German locomotives.

The cylinders, which are 16 in. in diameter by 22 in. stroke, are outside; and so also is the valve gear, which is of the "straight link" kind. One peculiar feature in the boiler of the engine we are describing is the great height given to the firebox casing, a feature which has been extensively adopted by Borsig, both for the purpose of giving additional steam room, and adding weight to the engine at the hind end. In addition to the raised firebox casing the boiler is also provided with a dome $24\frac{1}{2}$ in. in diameter and 3 ft. 5 in. high at the leading end. The front and back of the firebox casing above the firebox, and the smokebox tubeplate above the level of the tubes, are stayed by plates on edge secured to them by strong T and angle irons. The crown of the firebox is supported by being connected to transverse girders or stays, which extend across the firebox casing from side to side, and which thus serve as ties between these sides in addition to supporting the firebox crown.

The barrel contains 171 tubes, $1\frac{7}{8}$ in. in diameter, and 11 ft. $1\frac{1}{2}$ in. long, these tubes being of iron with copper ends. The heating surface of the firebox is 69 square feet, and that of the tubes (external) 930 square feet, making in all a heating surface of 999 square feet. The weight of the engine is 30 tons, empty, and 33 tons 14 cwt. when in working order, this latter weight being divided as follows:

	tons.	cwt.
On leading wheels................	11	14
On driving wheels................	11	6
On trailing wheels................	11	14
Total	33	14

The engine is provided with a six-wheeled tender, weighing, empty, $11\frac{1}{2}$ tons. In the year 1867, Borsig supplied ten engines, of the class we have described, at the price of £2,650 per engine and tender, and last December he received a further order for twelve such locomotives at the price of £2,533 per engine and tender. This type of engine is illustrated in "Engineering," May 21, 1867.

Mr. Scott Russell and Railway Ferries.—A little more knowledge of the facts, if not a reasonable amount of courtesy, would have saved some of our American newspapers, technical and otherwise, the discreditable mistake of abusing Mr. Scott Russell about what he has said and done regarding the introduction of railway ferries. The animus of the prime mover in this crusade against Mr. Russell may be observed in the wild way it goes about abusing that gentleman—for instance—by saying that the paddle engines of the Great Eastern were a failure, the fact being that they were a great success.

It seems to "rile" the American eagle beyond all endurance, that Mr. Russell designed and executed a ship to ferry railway trains across Lake Constance, and then described it in a paper before the Institution of Naval Architects, and urged a similar means of transit between England and France. And why? Because the same thing was done in America before! To be sure Mr. Russell said in his paper, "I must say that it is not me the English people have to thank for having made this experiment for them." He described a work of his own, and as his own, when a similar work had been done in America *before*. That is his offense. Suppose he had built a North river steamer or a twin screw, and had then urged their farther adoption and magnified the details of his own work without claiming credit for the general idea. Should we have gone mad over that? The railway ferry is as notoriously of American origin as the North river steamer or the twin screw. Or must Mr. Scott Russell begin by praising American genius every time he speaks of his constructions of the American type?

Mr. Russell *has*, on several occasions, described the Havre de Grace railway ferry as a brilliant feature of Amcrican practice, and he has always been the admirer and advocate of the many good features in American marine and mechanical construction. A native yankee, "with the stars and stripes grown onto his back," could not have rendered more frequent and hearty, and possibly not more graceful, tribute to the American practice than Mr. Scott Russell has rendered, in his many speeches and writings, for the last fifteen years. In fact, the greater part of the literature concerning the American steamboat practice has been made by Mr. Scott Russell and his son. For an American engineer to abuse Mr. Scott Russell is simply disgraceful.

Apparatus for Testing Rails.—Mr. Charles T. Liernur, formerly of Mobile, and now resident abroad, patented some nine years since, an apparatus of which the following is the specification:

"The object of my invention is to construct an apparatus in which the rail is subjected to a course of trials similar in its results to actual usage when laid upon the road. For this purpose I lay a circular track composed of 3, 4, or more rails (or pieces of rails), making a circle of from 20 to 30 or more feet in diameter. On this track I place a car supported by four, six, eight, or more wheels, all the axles of which point towards the center of the circular track. The wheels to be of the size, pattern and make as actually are to be used upon the road for which the rails are to be tested, and the car to be loaded with the weight per wheel equal to the greatest load they will have to sustain when in use upon the road. The vertical shaft to be well braced, and to be strongly attached to the car, so that when a rotary motion is given to the former, this motion will be participated in by the latter, a beveled cog-wheel being placed at the top or bottom of the shaft for the purpose of revolving it by means of a stationary steam engine placed near by.

"What is claimed as the invention is a railway car revolving by means of a center-shaft, and supported by four, eight, or more wheels, the axles of which point towards said shaft, and running said car upon a circular track of railway rails for the purpose of submitting both rails and wheels to a test of usage."

This plan has recently been proposed in England by other parties, and it is to be hoped that the experiment will be carried out.

Rolling Stock of the Central Pacific.—This Company has now running 150 locomotives. Besides these there are seven partially set up in San Francisco. There are several more contracted for, yet to arrive. The engines, in running order, are from eleven different makers, the largest number from one firm being 47 from McKay & Aldus, 28 from the Danforth Locomotive Company, 24 from the Schenectady, 10 from the Rhode Island, etc., only one being from Booth & Co., San Francisco. Two have drivers 3 ft. 9 in. diameter;

about twenty have six drivers 4 ft. diameter; twenty-five have six drivers 4 ft. 6 in. diameter; forty have four drivers ranging from 5 ft. 6 in. to 5 ft. diameter; sixty have four 5 feet drivers each; and two have four 5 ft. 6 in. drivers. Excepting two small locomotives, with two drivers each and 11 in. cylinders, 15-in. stroke, the locomotives run 16, 17 and 18-in. cylinders and 22 and 24-in. stroke. The engines under contract have six drivers, 5 feet diameter, 18-inch cylinder, and 24-in. stroke.

The Company owns 1,400 platform cars, nearly all of which have been made at Sacramento. The total number of box cars on the road is 360, with an increase at the rate of 30 a week. Of composite baggage, mail and express cars, there are 17 in work, and others constructing. Of hand cars and track cars and section cars, there are 123, and more making. The passenger cars are not very numerous; but besides ten in use, four are making in the shops and there are ten contracted for in the East. The Company also own a handsome family carriage. The sleeping cars will come from the east, and will be kept on those sections of road where night traveling is done.—*American Railway Times.*

Tie-spotting Machine.—This device, built by Mr. Jauriet, of the Chicago Burlington and Quincy shops at Aurora, is thus described by the "Chicago Railway Review:" Our readers are aware that rails are generally laid level upon the ties, with the result of bringing the whole weight of the car upon the inside of the rail and the inside of the inclined rolling surface of the wheel. Mr. Jauriet conceived the idea of laying the rail so as to incline inwards on the same level as the surface of the wheel. The old hand process of doing this, with adze, is slow, unequal, and costs more than it comes to. The tie-spotting machine—attached to a car and transported from place to place on the line—may be generally described as consisting of two vertical shafts, with knives attached, to which the ties are brought by means of a chain-feed. The knives are adjustable, so as to "spot" at an angle, or in the ordinary manner. The machine is operated by the engine attached; and requires, besides the engineer, six men to operate it, who do the work of from fifteen to twenty. A recent experiment resulted in the spotting of seventy-six ties in fifteen minutes.

Chicago, Burlington and Quincy Shops at Aurora.—We condense the following from the "Chicago Railway Review:" The present old works at Aurora are to be enlarged as follows: Car shop, 400 by 100 ft., two stories; setting up shop, 200 by 90 ft.; car machine shop, 100 by 90 ft.; car smith shop (nearly done), 200 by 90 ft.; paint shop, 200 by 90 ft.; drying kilns, lumber sheds, a tin and brass shop and a fire proof engine and boiler house. The old engine house (40 stalls) will remain, and another will be added. The present machine shop is 185 by 50 ft., stocked with Bement's and with Sellers' tools, among which are 26 lathes, 8 planers, and 7 drilling and boring machines. The present smith shop is 80 by 50 ft., and has a 4,000 lb. Bement-Davy hammer. The boiler shop is 60 by 50 ft. There are also a brass foundry, an oil house, and a rail repairing shop. The locomotive superintendent is Mr. C. F. Jauriet, and the superintendent of the car department Mr. W. W. Wilcox.

Chicago and Alton Shops at Bloomington.—The original shops at this place were burned in 1867. Temporary works were improvised within the old walls. The new works are more than half completed, and will have cost about five hundred thousand dollars. They are built of rough dressed stone, and have slate roofs on iron trusses. Gas lighting and steam heating are extended to every part.

The two engine houses (one completed) are 230 ft. in diameter, for 28 locomotives each. The machine shop will be 260 by 100 ft. with a wing 80 by 45 ft., and engine and boiler house attached. There is to be a transfer table outside of this building.—The smith shop is to be 200 by 100 ft.; the boiler shop 180 by 60 ft.; coal shed 125 by 40 ft.; iron house 80 by 50 ft.; foundry 210 by 60 ft., and cleaning room attached, 50 by 45 ft.

The car shop is 263 by 80 ft.; the car machine shop 200 by 75 ft. (2 stories), with outside transfer table and attached engine house; the paint shop 172 by 75 ft. A two story office and store building, 120 by 60 ft., is centrally situated.

The superintendent of machinery is Mr. J. A. Jackman; the superintendent of the car shops is Mr. Rufus Reniff.

Communication between Passenger and Guard to be enforced in England.—The Act for the Regulation of Railways, passed last session, provided that "after the 1st of April, 1869, every company shall provide and maintain in working order, in every train worked by it which carries passengers and travels more than twenty miles without stopping, such efficient means of communication between the passengers and the servants of the company in charge of the train, as the Board of Trade may approve. If any company make default in complying with this section, it shall be liable to a penalty not exceeding £10 for each case of default. Any passenger who makes use of the said means of communication without reasonable and sufficient cause, shall be liable to a penalty not exceeding £5." The Board of Trade have extended the time in order to afford further opportunity for further testing the merits of the numerous plans submitted to the companies.

Steel Rails.—Steel rails, it is reported, are to be laid on the entire length of the railroad from Paris to Marseilles. The change from iron to steel will require 137,000 tons of steel. From experiment made by the company, it has been calculated that in the vicinity of the stations iron rails will not last over eight or ten years. The steel rails, it is believed, will last thirty or forty years. The bridges are to be constructed of steel as soon as iron ores suited to the manufacture can be obtained in sufficient quantity.

The Erie Railway Company have completed 17,000 tons of steel rail on their road—not a broken rail since. They have purchased the New Jersey Iron Works and those at Elmira, and are now turning out about 400 tons of steel rail every month. Within a year the whole line will be relaid.—*American Journal of Mining.*

Locomotive Boiler Explosions.—No fewer than fourteen locomotives have exploded within the seven months ending June 1st, in the United States, killing twenty-nine persons outright and severely wounding a much greater number.

THE BROAD GAUGE, as regards the midland districts of England, is now a thing of the past, the Great Western Railway Company having ceased to run any broad gauge passenger trains between London and Birmingham, Wolverhampton and Liverpool. Already, too, on the branch between Reading and Basingstoke, the third rail has been removed, thus converting that line from a mixed gauge into an entirely narrow gauge line, and connecting the Great Western system with the London and South-Western Railway and the south of England. In addition to this, the whole of the broad gauge lines north of Oxford will immediately be taken up, removing in the midland counties the last trace of the system of one of the two great rival engineers, whose plans were so long hotly contested, and celebrated as "the battle of the gauges."

ANOTHER BRIDGE ACROSS THE MERSEY.—Messrs. William Low and George Thomas, civil engineers, have submitted to the Mersey Dock and Harbour Board a letter and plans, illustrating their scheme of crossing the Mersey by means of a railway suspension bridge between Liverpool and Birkenhead. It will consist of three spans, the center one 1,800 ft. in length, and the others 960 ft. each, and will be 140 ft. above high water mark. The bridge would unite the various railway lines in Lancashire and Cheshire. It will be under two miles long, and the total cost is estimated at £1,750,000. This would be the sort of thing to try our engineering mettle before we venture to bridge the Irish and British channels.

NEW INDIAN RAILWAY.—Operations in connection with the laying out of a new and important line of railway communication have just been commenced by a staff of British civil engineers. The line is designed to connect Carwar, on the Malabar coast, and the cotton districts of Hooblee and Dhawar, with the probability of its being carried through into the Madras Presidency. The line is to be designated "The Southern Mahratta and Mysore Railway." There will be formidable difficulties to contend with in "carrying the line up the densely-jungled ghaut," with an elevation of some 1,500 ft. The undertaking is to be carried out under the direct orders of the government.

THE ST. GOTHARD RAILWAY SCHEME.—It is rumored that, in addition to a subvention of 50,000,000f. to this scheme, Prussia is now ready to renounce her real or imaginary rights over the Swiss territory. The project has been well received in Switzerland, the Northern and North-Eastern Railways each contributing 9,000,000f., whilst the various German cantons will, it is expected, vote considerable sums in addition to the Federal subsidy.

THE CHANNEL BRIDGE.—M. Boutet's system of excessively long spans (3,282 yards) is being tested by *models* of one hundredth size, and upon the success of one, the "Journal Officiel de l'Empire Francais" says: "The project of a bridge over the straits makes each day further progress." * * * "The problem is resolved that bridges and viaducts of *every size* can be constructed in a single arch without piers from bank to bank!"

THE CREUSOT works have secured a fresh order for locomotives (fifty-five altogether) on Russian account.

LEGISLATION TO AID RAILWAYS.—During the five weeks' session of Congress, thirty-one bills were introduced in the Senate alone contemplating grants of public lands, bonds, or credit, or all three, to railway projects. The land grants proposed vary from one to eighty thousand sections in each case, and amount in the aggregate to about two hundred million acres.

RAILROADS VS. STEAMBOATS.—Drawing-room cars and steel rails are beginning to furnish those solid comforts which pleasure travelers have heretofore considered peculiar to steamboats. The roominess, upholstery and decoration of steamboats are all that could be desired, but there should be better ventilaton of dining-saloons, less early blowing off of steam, and more polite attendance.

FAST RUNNING.—Trains on the fast railway line between Liverpool and London can now be driven at the rate of fifty miles an hour, and the whole distance (200 miles) accomplished in four hours. There is no stopping for water, this being scooped up from troughs between the tracks while the train is running at full speed.

CONNECTICUT RIVER BRIDGE AT MIDDLETOWN.—The Keystone Bridge Company, of Pittsburgh, have contracted to build the new wrought iron bridge on the Boston, Hartford & Erie road at Middletown, Ct. It will be of 1,200 feet span, and will cost $176,000.

NEW BOOKS.

GEOLOGY OF NEW JERSEY. By authority of the Legislature. GEO. H. COOK, Geologist. 8vo. 899 pp., with portfolio of eight large maps. Published by the Board of Managers, 1868. New York: D. Van Nostrand.

This substantial volume gives the final report of the geological survey of New Jersey. The first survey of this State was made by Prof. Henry D. Rogers, the report of which was published in 1840. A subsequent survey was conducted by Dr. William Kitchell, geologist, and Prof. George H. Cook, assistant, during the years 1854, 1855 and 1856. But before the survey was completed, the failure of legislative appropriation compelled its close. The present survey was authorized in 1864, under Dr. Cook as geologist, and the result of the four years' labor and investigation of him and his assistant is given in this volume.

It consists of two distinct portions; the first, comprising about one-third of the volume, is a strictly scientific exposition of the geological formations found in the State. The work, in this department, has been mainly expended in extending the geological systems of New York and Pennsylvania into the corresponding formations of New Jersey. This has not been entirely without difficulties, because not a few unsolved mysteries had been bequeathed by the geologists of the neighboring States. The task, however, has been thoroughly done, and much light has been thrown on the intricate questions of fossil and lithological geology. In the appendix to the volume will be found some valuable catalogues bearing on these scientific inquiries.

The second portion of this work will be found to the general reader more interesting, and to those interested in developing the resources of the State, of the greatest value. It treats of the economical products of the State with a fullness and thoroughness which will be found equaled in no similar work. In this respect Dr. Cook and the managers of this survey deserve the thanks of the people of New Jersey and of her neighbors. To the agricultural public this complete exposition of the extent, the value and the characteristics of those marvelous beds of marl, will be most acceptable. Literally this fertilizer has for New Jersey turned the wilderness into a fruitful field. Many, for the first time, will find in this work the first systematic and satisfactory explanation of its value as a fertilizer. To those interested in mining, the chapters on the iron regions will be found especially acceptable. A special map is devoted to this region, and the location and direction of all the known iron beds are here laid out. It will surprise not a few to learn, from this work, that New Jersey, although standing twentieth in the scale of population among the States of the Union, furnishes one-eighth of all the iron, and in manufacturing iron stands fifth.

In other economic products New Jersey is unusually rich. One-half of all the zinc product of the United States is derived from her mines. Her clay beds furnish a vast variety of clay, from that suited for manufacturing common brick to that which will produce the finest porcelain. She has peat beds which will furnish a bountiful supply of fuel when the coal beds of Pennsylvania are exhausted. She has immense beds of sand, which is in demand for the manufacture of glass, fire-brick, and concrete stone. Her manufacturing interests are scarcely less important than her agricultural. Newark has grown to be a city of 120,000 inhabitants, and is the third city of the Union in the value of its manufactured products.

Situated as New Jersey is, between the two greatest markets of the United States, she can never fail to be one of the most important sections of the country. Cheapness of transportation, the certainty of a market even for the most perishable products, the fertility of her soil, the industry, thrift and intelligence of her inhabitants, ensure for New Jersey a rapid development of her resources, and an unexampled career of prosperity. To this rapid development this valuable report of Dr. Cook cannot fail largely to contribute. The Legislature has wisely decided to continue the survey under the same admirable management for an additional period.

Modern Practice of the Electric Telegraph.—A Handbook for Electricians and Operators. By Frank L. Pope. New York: Russell Brothers, Publishers, 28, 30, and 32 Center street.

During the quarter of a century which has elapsed since the introduction of the electric telegraph in the United States, those engaged in its service have been almost entirely dependent upon verbal instruction, and long practical experience, for a thorough technical knowledge of their profession. The works heretofore published on the subject have been of a popular rather than of a scientific or practical character, or else of so elementary a nature as to be of little service except to very inexperienced students.

The work before us, though very concise, is a treatise suitable for the practical electrician and telegraph operator; but it will also be found serviceable to the student as well as to the more advanced electrician. Its author, who, though a young man, is a telegrapher of many years' experience, and has a thorough scientific knowledge of all that relates to the telegraph, goes very fully into the various branches of the subject—batteries, magnets, circuits, and insulation. The book contains a very complete description of the Morse or American telegraph system, explains the testing of telegraph lines, gives notes on telegraphic construction, and hints to learners, and concludes with very copious notes on various minor details.—*American Artizan.*

Lehrbuch der gesammten Tunnel-baukunst. Von Franz Rziha. Ernst and Korn, Berlin, 1868.

The fourth part of the second volume of this magnificent work of Rziha's, which we have noticed at length in past pages of the "Practical Mechanics' Journal," has appeared; and all we need say of it is that it fully sustains the reputation of the preceding parts.

In the present part the Belgian. German and Austrian systems (for they all differ a good deal) of tunneling are fully described and critically compared. This is followed by an elaborate comparative critique and estimate of costs, of timber-frame tunneling, with a chapter or two on the methods of lining with masonry under diverse conditions; and these lead on to the commencing chapters, in which the author is about to describe his own peculiar system and construction of cast and wrought-iron moveable framing for tunneling without timber, of which we before now gave a tolerably complete sketch to our readers.—*Practical Mechanics' Journal.*

Leitfaden zur Bergbaukunde &c. Von Bergrath H. Loptner. Bearb. u. herausg. von A. Serlo: Erste Liefrg.

We may fitly place this work after that of Rziha, for it treats of a very analogous subject. Tunneling and shaft-sinking for railways have much in common, and have in fact borrowed much in practice from level and adit driving and shaft-sinking for coal and other mining. These last are the operations here treated of, and treated of with the ability we are prepared to expect from the reputation of Bergrath Lottner, well known in Germany for his grand maps and sections of the coal formations of Westphalia, &c., and as a Professor of Mining in the Royal Mining Academy of Berlin. The present part treats mainly of sinking and driving through various "ground," and includes all the new machinery for boring and holing each, and the new and old explosive agents. The work will be completed in three large parts (or volumes, we may almost call them,) with many illustrations by excellent woodcuts; and the successive parts will embrace every head of subject belonging to the miner's art, so far as the entering the ground, securing it, and keeping the shafts, &c., level water and foul air free, are concerned. It excludes, as belonging to metallurgy proper, the treatment of the material, of whatever sort, extracted by means of the excavations made.—*Practical Mechanics' Journal.*

The Manufacturer and Builder. May, 1869: New York. Western & Co., 37 Park row.

This monthly journal contains 78 columns of interesting matter and numerous engravings for 15 cents—a marvelously cheap technical publication. The articles in the May issue for instance, are 60 in number, 10 of which are illustrated; the following are of special interest: The Telephone, Boiler Explosions, Beton building, Hydraulic Mortar, Hydrogenium, Magenta (analine color), Church Architecture, Interior Decoration. A journal giving so much information at such a price, deserves success.

Woodward's National Architect; containing 1,000 original Designs. Plans and Details to Working Scale, for the Practical Construction of Dwelling Houses for the Country, Suburb and Village. With full and complete sets of specifications and an estimate of the cost of each design. By George E. Woodward, Architect, Author of "Woodward's Country Homes," "Woodward's Cottages and Farm-houses," etc., etc., and Edward G. Thompson, Architect. New York: George E. Woodward, 191 Broadway.

High rents and close quarters are driving the inhabitants of cities like New York into the country with unprecedented rapidity, and, thanks to our railroads, it is now nearly as easy to live twenty miles out of town as to live in the upper part of the city. The loss of time is about as great in the one case as in the other, while the advantages of a real country residence are so great, especially to children, that no sensible man will stay in the city if he can possibly make his escape. To those who contemplate taking a part in this exodus the work we have just recited will prove invaluable. It is filled with chaste designs for conveniently arranged dwellings.

The plan of the work embraces designs for houses of moderate valuations, estimated at New York prices as a basis, with such detail prices as will enable one to ascertain the cost, in his own locality, by comparison with the different rates of prices that always exist in different sections of the country.—The forms of specifications given are such that they may be adapted to any of the designs, so that full and final estimates can be obtained from local builders. To builders and architects residing in the country this work must prove invaluable.—*Manufacturer and Builder.*

Zell's Popular Encyclopedia and Universal Dictionary. Philadelphia: T. Ellwood Zell. Part XI. 1869.

It is not many years since a comparatively small cyclopedia sufficed to contain exhaustive articles on almost every branch of human knowledge. How has all this changed! Some of our modern cyclopedias which deal with a single science contain as much matter as the first edition of the "Encyclopedia Britannica." At the same time, the tendency is toward condensation; and in the popular encyclopedias of to-day, we find dismissed in a single line a subject which a few years ago would have been expanded into a page. This holds particularly in relation to the well-known and deservedly popular cyclopedia published by the Messrs. Chambers, of Edinburgh. The same feature is prominent in the cyclopedia before us. In short, it combines the characters proper to both a cyclopedia and a dictionary. Thus we find not only such nouns as *ambition, ambler, ambling,* but adjectives like *ambitious* and adverbs like *amblingly.* On the other hand, such articles as ammonia are extended far beyond the limits of a mere definition, and present all the really valuable facts that are of interest to popular readers. We see that the editor has wisely avoided the futile attempt to supply the wants of professional men, who must, in all cases, rely either upon their own knowledge, or upon the assistance of purely technical works. We refer to such subjects as alcoholometry, alkalimetry, etc. In most popular cyclopedias, these purely technical departments of the chemist's art are either treated at an unreasonable length or described so superficially as to lead to error. The editor of "Zell's Cyclopedia" has avoided both these dilemmas. The publishers engage that the cost of the work, when completed, shall not exceed $25, and we know of no means of procuring the same amount of valuable information at such an easy rate.—*Manufacturer and Builder.*

Smoking Fires, their Cause and Cure. By the Rev. Alexander Colvin Ainslie, M.A., Vicar of Corfe, Somerset. For sale by Van Nostrand.

"Where there is smoke there is fire," says the adage, but where there is smoke there is too often no light—to point out its cause or remedy—if the smoke be that of a house chimney. The puffing back, or even in some cases streaming back of smoke into a room, can be avoided or cured, and ought never to happen, though the fact is that there is scarcely a building even of the first class in which some of the chimneys do not smoke. That it is due in great part to the practical ignorance of first principles on the part of architects and housebuilders, and to the carelessness of both to almost everything but to getting "the job done and paid for," is certain.

Parson Ainslie has written by far the best treatise on the subject that has been produced. "The ascent of heated air and smoke is governed by certain known laws," he says in his introduction; "and the object of the following pages is to explain those laws as concisely as possible, and to point out the causes which most commonly modify or interfere with their action, and produce results apparently contradicting scientific theory." He does so in a brief and lucid manner, and then applies these laws to nearly all the examples of smoky chimneys occurring or likely to occur in practice, and deduces rules for guidance that even the least philosophical of bricklayers can scarce fail to comprehend and readily be guided by.—*Practical Mechanics' Journ.*

Annual of Scientific Discovery, etc., for 1869. Edited by Samuel Kneeland, A. M., M.D., etc. 12mo, pp. 377. Boston: 1869. Gould & Lincoln.

This old acquaintance is always an agreeable reminder of its predecessors of former years, as well as of numerous discoveries, facts and principles in various departments with which we are, as fellow laborers in the great field, more or less familiar, but which it is always pleasant to find marshaled in an orderly and compact manner, under their appropriate heads. Every such review of the year must of necessity be imperfect and unequal as an exposition of all that has been done, but even a cursory glance at Dr. Kneeland's Annual will show any fair-minded reader the vast variety of topics which now engage the attention of scientists, and the pains-taking care with which the editor has endeavored to present the most important results. The notes by the editor, forming an introduction to the volume, give an interesting summary of the progress of science for 1868.—*American Journal of Science and Art.*

MODERN SCREW PROPULSION. By N. P. BURGH, engineer. London: E. and F. N. Spon, 48 Charing Cross. For sale by D. Van Nostrand, 23 Murray street, New York.

Mr. Burgh's treatise on screw propulsion, which was to have been completed in fifteen parts, has been extended to sixteen. This extension has been decided upon in order that the work may embody some very recent important matter on screw propellers, which has been exclusively given to the author by our leading marine engineers. The author has thus exercised a wise discretion in thus extending his work, and to which none of his readers will object. Parts XIII, XIV and XV of this treatise are now before us; they are chapters on a new principle of the screw propeller, by Mr. Arthur Rigg, who has made some very interesting experiments with the screw, the results of which he here embodies. Mr. W. Langdon supplies a chapter on thrust blocks, and Mr. Burgh follows with another on the same subject. In Chapter XX, Mr. Burgh reviews comparatively the whole family of modern screw propellers as constructed by our principal marine engineers. In the succeeding chapter, Mr. Burgh gathers into a focus the opinions and ideas of all the engineers who have contributed to his treatise. In this chapter, the last page of Part XV finds us. The illustrations of these three numbers consist of lifting frames for the screw propeller, the feathering screw of the "Aurora," and the details of the methods of screw propulsion adopted in various other vessels.—*Mechanic's Magazine.*

THE PAINTER, GILDER AND VARNISHER'S COMPANION. Thirteenth edition, revised, with an Appendix. Philadelphia: Henry Carey Baird; New York: S. R. Wells, 389 Broadway.

This book contains rules and regulations in everything relating to the arts of painting, gilding, varnishing, glass-staining, graining, marbling, sign-writing, gilding on glass, and coach painting and varnishing. It also gives tests for the detection of adulterations in oils and colors, and a statement of the diseases to which painters are peculiarly liable, with remedies. It is several years since the first edition of the book was published, and as new editions have been gotten up, additions have been made to bring the work up to the time. The appendix added to the present edition comprises descriptions of a great variety of additional pigments, their qualities and uses, with additional information on dryers, and also contains an explanation of Chevreul's principles of harmony and contrast of colors.—*American Artizan.*

TREATISE ON THE POWER OF WATER. By JOSEPH GLYNN, F. R. S. D. Van Nostrand: New York, 1869.

(Second Notice.) We have had occasion, since receiving this book, to study the literature of water power, professionally and commercially. This fact, together with the corresponding fact that our difficulties have been solved by reference to this book, prompts us to acknowledge its merits in a more decisive form.

There are rules, in the professional pocket books, for measuring the *flow of water*, but it has been reserved for people who sell water, or pay for it, to observe a notable variation in the results of *position* and *shape* of orifices through which water is discharged. If all the information extant is not embodied in the work under consideration, there is enough to solve all ordinary cases.

In addition to the usual historical notice and to the wonted tribute to the power and functions of water, this book contains much interesting information upon the sources of water supply and upon water wheels. It is quite well illustrated and the subject appears to have been very carefully and exhaustively investigated by the author.

THE AMERICAN EXCHANGE AND REVIEW.—A miscellany of useful knowledge and general literature. Especially devoted to Finance, Mining and Metallurgy, Insurance, Railways and Transportation, Manufactures, Patents, Trade, Commerce, Art, Joint Stock Corporation Interests, Physics, Social and Economic Science. Fowler & Moon, 521 Chestnut street, Philadelphia.

This is a monthly of considerable value to students in the subjects mentioned above, and of no little interest to the general reader. It is a sort of connecting link between our literary and scientific serials. The department of mining and metallurgy is conducted by Prof. H. S. Osborn of Lafayette college, and is specially complete and interesting.

A SAPPER'S MANUAL, FOR ENGINEER VOLUNTEER CORPS. By Captain FRANKLAND, R. E. Published under War Office authority.

HINTS ON HOUSE DEFENCE AND BLOCKHOUSES. By Captain YOUNG, 18th Royal Irish. Wellington, New Zealand: Lyon.

MISCELLANEOUS.

SILVER PLATING—OLD AND NEW PROCESSES.—The following is compiled from the Birmingham correspondence of "The Engineer." The old-fashioned process was this:

An ingot of copper, ordinarily weighing about nine pounds, and which had an alloy of brass of one-fifth its weight, was first planed and then filed to a perfectly level surface on both sides; the ingot of silver, containing about 3 per cent of alloy, was rolled to the required thickness for the different qualities of metal to be plated. This was cut into suitable lengths, the weight of the piece of silver varying according to the quality, the lowest being about 16 dwts. for the 9 lbs. of copper for one side only, and increasing to 6 oz or 8 oz. The piece of silver was about $\frac{1}{8}$ in. less than the surface of the copper. It was scraped quite clean on the side next to the copper, great care being necessary that every imperfection should be removed; the two bright surfaces were then laid together and "bedded," by placing a heavy piece of iron on the silver, and striking it with a sledge-hammer till every part of the two surfaces touched. A strong piece of sheet copper was then laid on the silver, to keep it from rising during the process, and also to prevent the wires, which were used to bind the two pieces together from cutting the outer parts of the silver plate. A solution of borax was then laid round the edges of the silver to act as a flux. The ingot thus prepared was then heated in a small furnace until a bright line round the edges of the silver indicated that the union was effected. The ingot was then carefully removed from the fire and cooled gradually. When cold, the wires were cut, the copper plate taken away, the edges carefully filed, and the plated ingot was then ready for the roller.

In the year 1840 the plated ware trade underwent a complete revolution. The process just described was superseded by an invention of Messrs. Elkington, now so well known as electro-plating, by which silver is deposited with accuracy and certainty by the aid of galvanism. This process is essentially dependent upon the original discovery of Volta, the alchemist, in 1799, on which various inventions had been subsequently based. Messrs. Elkington were, however, the first to apply the process successfully to the purposes of practical industry, and their enterprise in this direction took the old-fashioned platers by storm. The opposition they encountered was immense.

The process of plating at Messrs. Elkington's factory is thus described: The article having been thoroughly cleansed, it is plunged first of all into a solution of cyanide of mercury to prevent any oxidation, as well as to secure a perfect adhesion in the plating. It is then transferred to the plating vat, which is divided by plates of silver into regular compartments, the articles being suspended on brass rods with copper wire, and so arranged as to expose an equal amount of surface in each compartment to receive the deposit of silver. The operation of plating is so nicely regulated that the rate at which the silver is being deposited is correctly known, and the large amount of 24 oz. per hour is deposited, perfectly smooth and extremely hard. This, with the thickness of silver, accounts for the great durability of the articles manufactured by Messrs. Elkington. There are several large vats in use, so that some idea may be formed of the large amount of silver deposited in one day. When the article has been in the vat a sufficient length of time it is taken out, rinsed in cold water, and dried. After that it is carefully weighed, and the exact amount of silver on the article is at once seen and registered. In addition to the ordinary batteries used in plating, a very large magneto-electric machine is in constant work.

Asbestos Paper and Cloth.—The Florence correspondent of the New York "Times" (Mar. 27) gives a long account of this new manufacture. Crude asbestos resembles bleached hemp, with long, shining fibres, which may be twisted into threads and woven into cloth, or converted into pulp and made into paper. Asbestos is plentiful in various parts of Italy, and the new processes of treatment have been introduced there. The ancients, however, used asbestos cloth for embalming, and specimens of it are found at Pompeii. The great value of paper made from this substance is its indestructibleness, either by fire or by decay.

Heat of the Stars.—Mr. Huggins has been making experiments with the view of ascertaining the heat of the stars. He employed a thermopile, the face of which was placed in the focus of a telescope. The pile was connected with a galvanometer. The following results were obtained: The mean of a number of observations of Sirius, which did not differ greatly from each other, gives a deflection of the needle of 2°. The observations of Pollux $1\frac{1}{2}$°. No effect was produced on the needle by Castor. In one observation Arcturus deflected the needle 3° in 15 minutes. Regulus gave a deflection of 3°. The observations of the full moon were not accordant. On one night a sensible effect was shown by the needle, but at another time the indications of heat were excessively small, and not sufficiently uniform to be trustworthy. It should be observed that several times anomalous indications were observed, which were not traced to the disturbing cause. The results are not strictly comparable, as it is not certain that the sensitiveness of the galvanometer was exactly the same in all the observations; still it was probably not greatly different.

Magnesite or sepiolite, better known as "meerschaum," is found in masses in stratified alluvial deposits among serpentine. It is a product of the decomposition of carbonate of magnesia, its composition is silica 60.8, magnesia 27.1, water 12.1 in 100 parts. Meerschaum is found in Asia Minor in the plains of Eskii-Sher or Eski-Schehir, in Greece, at Egribos in the island of Negropont, in the isle of Samos, at Kiltschik in Natolia, in the Crimea, at Hrubschitz in Moravia, in Morocco, at Vallecas in Spain (where it is used as a building stone), at Baldissero in Piedmont, in Cornwall, in France (in the departments of the Gard, of Seine et Marne, and of the Seine); but the most remarkable quarries worked at present are situated at Brussa, at the foot of Mount Olympus. When first dug up it is damp, soft and greasy. The Tartars use it as soap to wash linen, and the Arabs of Algeria in the manner in the Moorish baths. In masses it floats on water. The color is grayish-white, white, or with a faint yellowish or reddish tinge.

Coal Ashes as a Fertilizer.—A series of experiments conducted at the Museum of Natural History, Paris, during the past year, by Professor Naudin, on the value of coal ashes as a fertilizer, has resulted in the conclusion that they are neither a manure nor even earth of the most infertile quality. An opinion to this effect has prevailed in this country pretty generally, but it is certain that upon heavy clays, they act as a disintegrator if nothing else. This effect is not, we are convinced, merely mechanical, as a very small amount of coal ashes is sufficient to destroy the adhesiveness of a large amount of clay. At least this was the case in a recent experiment of our own, tried in accordance with the advice of one of the most accomplished florists in New York State. By the application of sifted coal ashes with a very small proportion of well rotted horse manure, we were able to make a thrifty flower garden the first season, upon one of the stiffest soils it has ever been our lot to own.—*Scientific American.*

Mr. Andrew Shanks, inventor of the double slotting drill, and designer, and maker of much heavy and ingenious machinery, well known in England, died recently at Hastings. "Engineering" says, and we can certainly indorse the following: "His universal readiness to assist in carrying out improvements, or afford information on engineering subjects, are too well known to all who ever had occasion to apply to him, and his death, with such a vast amount of unrecorded practical information, must be regarded as a serious loss."

Boiler Explosions.—During the past seven months there have been in the United States sixty-one boiler explosions, the great majority of them involving loss of life.

REFORMED SCHOOLS.

Now that college students can rival the ignoble crowd with bat and oars, university culture may be safely advanced another stage, looking to the day when the collegian shall compete with the outsider in other practical branches of knowledge. We deprecate the modern, almighty dollar theory of an exclusively "business" education; we would not *substitute* the most polished scholarship in discount and bookkeeping for the grand old university literature, classical and polite.

The old idea that classical knowledge is an aim and end of education, was, perhaps, more nearly correct than the later idea that classical culture is the only suitable and proper means of working and developing the mind. In this utilitarian age of speculation and greed, of sensational literature, sharp practice and vulgar show, the greatest amount of old fashioned scholarly culture that we can force upon our young men and women will hardly neutralize the leveling tendencies of the times.

But while our schools should not ignore polite culture, they certainly should not neglect practical education. Under the theory that the mind is a machine to be developed, or a power to be disciplined, rather than a storehouse to be filled, are we not overlooking the advantages of positive, technical knowledge? Our new school professors indeed proceed upon the *theory* that the mind can be as well disciplined by practical as by classical studies. But are modern studies practical? Are the greater number of modern English text books really more available to the graduate who has a living and a name to win, than the old Latin ones? There must be one-idea scholars in every branch of knowledge, but are the sublimated mathematics of our "practical" schools either a better universal digester or a better universal resource than Greek roots? If not, then the old fashioned studies have equal advantages in the matter of culture, and the additional dignity of age and scholarly association.

We believe that a comparison of the knowledge wanted in the practical world, with the knowledge furnished in the practical schools, will convince the candid inquirer, 1st. that the course of study is not always well selected; and 2d—and of this we wish particularly to speak—that the books, lectures, references and prescriptions in the departments of learning that purport to be practical and of immediate and every day value, are incomplete and inadequate.

Immediately upon his graduation, in whatever direction his tastes, ambition or necessities may lead him, the young man encounters the *business formulæ* of commerce and production, of which he is ignorant. He may be versed in the elements of political economy, mathematics and chemistry, but he has still to master the rules and forms of practice. He may know the principles of communication with the world, but he has yet to learn the dialects and idioms of business. Mere muscular Training is not more essential to success in athletic sports than mere mental Culture to the triumphs of mind; but Skill plucks the laurels from their brows on the world's playground as well as in the world's workshop. The Latin salutatorian and the Greek versifier of the ancient university, are not much greener than the graduates of "practical" schools when they come to grapple with the first year's work in a business office. This state of things is unnecessary and wrong in every regard. Study is not less a mental tonic because it fits a man to keep books, to write business papers and to buy or make good machinery. And the notorious greenness of graduates in practical affairs, deters many young men from commencing with a theoretical education. It is a grave question in many minds whether skill and training in the arts of life should not precede and lead up to a knowledge of the sciences.

The argument against the dead languages as a means of mental training, when the world is full of live subjects equally difficult to master, is just as valid against practical subjects when taught in an unpractical manner. A man may study mathematics all his life and not be able to earn his bread in a merchant's office or an engineer's drawing room. He may even master all the text books in mechanics and not be able to construct an economical steam engine. We are deceived by the names and cheated of the substance of practical learning. Our universities may well copy the course of training in our *commercial* colleges and our foremost *technical* schools, and so adorn a scholarship that will pay, with the graces of polite and classical culture. At least let us not abandon the studies that not only disciple the mind but liberalize the sentiments and refine the social and intellectual relations of life, until we are prepared to substitute studies that really teach men how to live and thrive—studies that directly and immediately advance the battle of mind against matter—studies that are practical in substance as well as in name.

BLACK LEAD, which has only been used as a lubricator for wooden machinery, and for wood piston packing, is now applied by M. Deloris, in France, to every kind of machine, from the heaviest vehicles to the most delicate watch-work, so dispensing with the use of oils and grease of all kinds. If plumbago can be successfully applied to railway carriages, a great saving to the companies will be effected. It is said to be used with many vehicles in Paris, and in machinery at several factories, and seems to give satisfaction.

PAPERS ON CONSTRUCTION.

No. IV.

IRON ROOFS.

By Lieut. C. E. DUTTON.

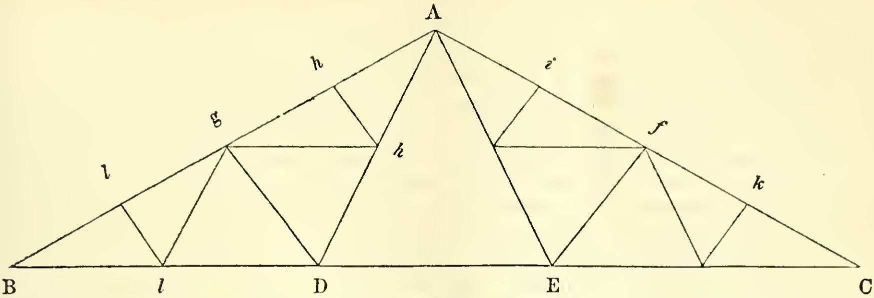
(Continued from page 583.)

A roof owes its stability to a series of similar frames called trusses. The most common form of roof-truss is an isosceles triangle, of which the two equal sides supporting the roof covering are called principal rafters. The rafters are subject to compressive and transverse stress, and are constructed accordingly. The third side is subject only to tensile stress, and is called the tie-rod, or tie-beam, and, in the case of an iron roof, consists of one or more rods of round iron. The stresses which this truss is required to withstand are, 1st, those arising from the weight of the entire roof structure, and 2d, those caused by the weather, viz: wind and snow. For the resistance to these forces the rafter may be treated as an inclined beam supported at each end, and, if desirable, at intermediate points, the lower end abutting against the extremity of the tie-rod, and the upper end against the upper end of the opposing rafter.

The rafters are made either of common rolled T iron, or of two pieces of L, or angle-iron, riveted in such a manner that they form a T. The flange is placed upwards for several reasons, that being the position of gratest strength in a beam of that particular cross-section, besides being most convenient for the attachment of purlins, braces and struts. The tie-rod has a jaw at each end, which receives the web of the rafter to which it is pinned.

In roofs of great span, in order to give the rafter the requisite rigidity, secondary trussing must be resorted to. But in such a case the general principle of the truss is in no respect changed, the variations being merely those of detail and supplementary. The two rafters and the tie-rod still remain, but with the addition of new parts for carrying out the same general design. To secure proper stiffness the rafter is supported in the middle by a strut, which thrusts against a point held in stable equilibrium by two or more forces, whose resultant is equal and opposite to the thrust. Fig. I is a compound truss of the commonest form. The junction of each part will readily suggest itself upon a simple inspection of the diagram.

Fig. I.



Assuming that in a roof of given length, measured along the ridge, the rafters are placed at equal distances apart, the weight of superstructure to be sustained by each will be equal to the weight of material between any two consecutive rafters. To this must be added the weight of the rafter itself, with its appurtenances, and a suitable calculation should be made of the maximum amount of snow which may accumulate upon it, and of the force of the wind. Of these the weight of the rafter is an unknown quantity. The others may be readily determined after the pitch, or slope of the roof, is decided upon.

To determine the stress upon the various parts.—Let W represent the weight of a section of the roof between two consecutive principles. Each rafter will then support one half this weight. The mutual support afforded at the apex is transmitted to the walls at B and C, so that each wall sustains one-half the load. Although the load is uniformly distributed, we may consider it as concentrated at A with a vertical resultant $= \frac{1}{2}$ W. This resultant may be resolved into two components acting along the rafters A B and A C with forces $= \frac{1}{2} (\frac{1}{2} \text{W cosec } \phi)$, in which expression ϕ represents the angle of the slope of the roof. Since cosec. $= \frac{\text{R}}{\text{sin.}}$ we may put the expression for the thrust into the following form: $t = \frac{1}{4} \frac{\text{W}}{\text{sin. } \phi}$ This thrust is opposed by two forces, one of which is the upward resistance of the wall; the other, the pull of the tension rod. Hence we may divide it into two components, r' and r.

$$r' = t \text{ sin. } \phi = \frac{1}{4} \frac{\text{W}}{\text{sin. } \phi} \text{ sin. } \phi = \frac{1}{4} \text{W}$$

$$r = t \cos \phi = \frac{1}{4} \frac{\text{W}}{\text{sin. } \phi} \cos. \phi = \frac{1}{4} \frac{\text{W}}{\text{tan. } \phi}.$$

In the equation $r' = \frac{1}{4}$ W, only half the weight is actually considered, viz: that portion which is directly supported at the apex and transmitted by the thrust of the rafters to the top of the wall. But each wall supports directly $\frac{1}{4}$ W, which, added to the quantity obtained. makes $\frac{1}{2}$ W, which represents the entire supporting force of each wall.

The stresses sustained by the minor component parts of a compound truss must be determined separately, and for this purpose we must ascertain the distribution of the load over the points B, l, g, h, A. Since $\frac{1}{2}$ W is equally distributed over each rafter we may consider B l, l g, g h, h A, as so many separate, uniformly loaded beams, resting upon their respective points of support, with stresses equal to $\frac{1}{16}$ W at each end, so that the direct stresses as thus considered are, at A and B $\frac{1}{16}$ W each, and at l, g, h, $\frac{1}{8}$ W each. But the stresses at l and h are transmitted through the struts $l\ l'$, $h\ h'$ to their respective suspending rods (braces), and by the braces to the points B, g, A. A simple inspection of the diagram will show that the resultant of the pulls along $g\ h'$ and $g\ l'$ will be equal to $\frac{1}{8}$ W along g D. This stress, added to the direct stress at g, gives $\frac{1}{4}$ W for the total stress at that point. The tension along $g\ h'$ and A h', $g\ l'$ and B l' is, in each case, $\frac{1}{16} \frac{\text{W}}{\text{sin. } \phi} \cos. \phi$. By the same reasoning it will appear that the tension along B D and D A must be $\frac{1}{8} \frac{\text{W}}{\text{sin. } \phi} \cos. \phi$. It has already been shown that the tension along B C, due to the primary thrust of the abutting rafters, is $\frac{1}{4} \frac{\text{W}}{\text{sin. } \phi} \cos. \phi$. Hence the pull along B l is $\frac{\text{W}}{\text{tan. } \phi} (\frac{1}{4} + \frac{1}{8} + \frac{1}{16})$; the pull along l 'D is $\frac{\text{W}}{\text{tan. } \phi} (\frac{1}{4} + \frac{1}{8})$, and the pull along D E is $\frac{\text{W}}{\text{tan. } \phi} (\frac{1}{4})$.

It is apparent that the braces produce a compressive stress in the rafter in addition to the direct thrust caused by the weight of the opposing rafter. A g D and B g D may be considered as triangles of forces in equilibrium. By taking one-half the weight imposed upon the strut g D $\frac{1}{8}$ W, we have at once the means of determining the forces acting upon the other sides of each triangle. It has already been shown that the pulls along A D and B D are $\frac{1}{8}\,\frac{W}{\tan.\ \phi}$, and the compression of the rafter due to these two pulls must be $\frac{1}{8}\,\frac{W}{\tan.\ \phi}\cos.\ \phi = \frac{1}{8}\,\frac{W}{\sin.\ \phi}$ In the same way it may be shown that the compression produced by the braces A h' and $g\ h'$, $g\ l'$ and B l' is $\frac{1}{16}\,\frac{W}{\sin.\ \phi}$. Hence the total compression is

$$P = \frac{W}{\sin.\ \phi}\left(\tfrac{1}{4} + \tfrac{1}{8} + \tfrac{1}{16}\right).$$

The pressures upon the struts g D and $l\ l'$ are respectively $\frac{1}{8}$ W and $\frac{1}{16}$ W.

Many trusses are constructed with the tie-rod raised above the horizontal, as in Fig. II. the tension on the rod D E will always vary inversely, as its perpendicular distance from A, *i. e.* tension on B C : tension on D E :: A b': A b. The tension on the braces may be formed as before.

An excellent method of trussing, and one very extensively employed in England for moderate spans, is shown in Fig. III. It is known as the king and queen post truss, $a\ a'$, $b\ b'$, $c\ c'$, &c., are struts, and $a\ b'$, $b\ c'$, $c\ d'$, &c., are suspension rods, and their arrangement is such that B d' c, B c' b, B b' a, &c., may be considered as braces holding each its own strut. Assuming, as in the first example, that B d, $d\ c$, $c\ b$, &c., are separate beams, each supported at its extremities, then (assuming also that there are four secondary trusses), the distribution of the load is as follows: $\frac{1}{5}$ the weight of the rafter, or $\frac{1}{10}$ W, rests directly on each of the points a, b, c, d, and $\frac{1}{20}$ W on A σ B. By means of the braces and struts one-half the weight at d is transmitted to c, $\frac{2}{3}$ the weight at c to b, $\frac{3}{4}$ the weight at b to a, and $\frac{4}{5}$ the weight at a to A. If we resolve the thrust along any one one of the struts, for

Fig. II.

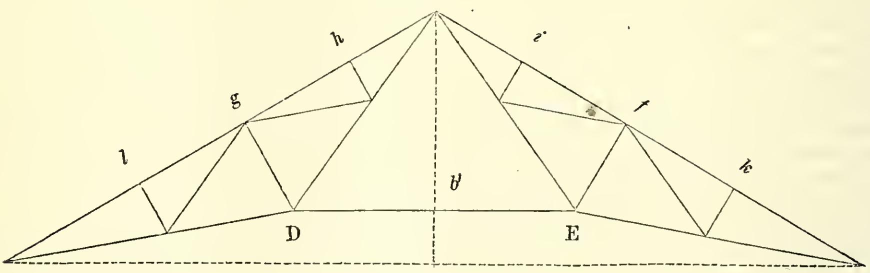


Fig. III.

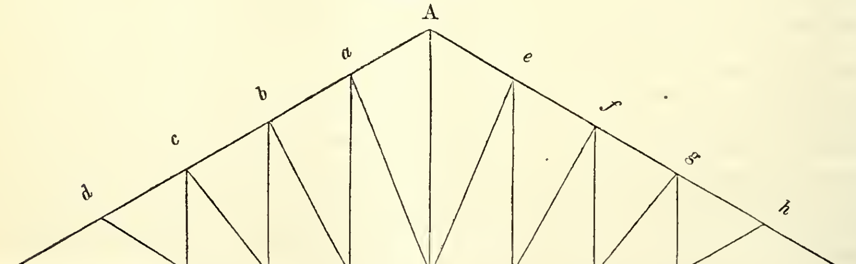

We have ascertained that the tension on a rod from B to C would be $t = \frac{1}{4}\,\frac{W}{\tan.\ \phi}$. An inspection of the diagram will show that instance $b\ b'$, into the two components which withstand it, viz: $b'\ c'$ and $c'\ b$, the former will represent the additional pull on the tie rod, and the latter the pull on the queen-post $a\,b'$ caused by the stress at b'. Treating the stresses at the other points in the same manner, we shall find that they all give rise to equal additional pulls on the tie-rod. But the pull on the tie-rod produced by the strut $d\,d'$ is $\frac{1}{20}\cdot\frac{W}{\tan.\phi}$. Hence the tensions on the tie-rod are

$$\text{Between } a'\,b' = \frac{W}{\tan.\phi}\left(\tfrac{1}{4}+\tfrac{1}{20}\right).$$

$$\text{“} \quad b'\,c' = \frac{W}{\tan.\phi}\left(\tfrac{1}{4}+\tfrac{2}{20}\right).$$

$$\text{“} \quad c'\,d' = \frac{W}{\tan.\phi}\left(\tfrac{1}{4}+\tfrac{3}{20}\right).$$

$$\text{“} \quad d'\,B = \frac{W}{\tan.\phi}\left(\tfrac{1}{4}+\tfrac{4}{20}\right).$$

and the tensions on the queen-posts are,

$$\text{on } c\,d' = \tfrac{1}{10}\ W$$
$$b\,c' = \tfrac{3}{20}\ W$$
$$a\,b' = \tfrac{1}{5}\ W$$
$$A\,a' = \tfrac{1}{2}\ W.$$

The king post A a', it will be observed, receives the stresses from two struts—$a\,a'$, $e\,a'$.

The few illustrations we have given contain the main principles involved in the operation of. forces upon the frame work of triangular roofs of moderate size. The variations of detail may be almost infinite, and they are sometimes very complicated, but are easily reducible to simple thrusts and pulls, and to parallelograms of forces.

In iron roofs the trusses described are made to serve the purposes of both principal and common rafters. The distances between them may vary, according to circumstances, from 3 ft. to 30 ft. In the latter case, and in all cases where a considerable interval between rafters is desirable, the purlins must be trussed. The foot of the rafter may be received into a cast-iron saddle bolted to the wall plate, and the main tie-rod may be jawed and riveted to the web of the rafter, or may pierce the casting and be fastened by a key or pin, or thread and nut. These matters of minor detail are always highly variable and are determined simply by considerations of convenience. In this climate and latitude, provision should be made for varying the length of the main tie to adapt it to the wide ranges of temperature, and this is best accomplished by a swivel-nut in the center.

The purlins are bars of iron, crossing the rafters at right angles, and to them the roof covering is directly attached. The most suitable form is ordinarily a double flanged bar or rail, of such a length that its ends shall rest upon rafters.

The roof covering may be wood or iron. In the former case it is shingled or tiled, and in the latter corrugated iron is by far the best material. Corrugated iron may be obtained in sheets of any length not exceeding 8 ft., and the length of the sheets should be a multiple of the length of the rafter, added to the proper allowance for overlaps. Thus, a rafter 27 ft. long will require four lengths of 7 ft., 4 in. being allowed for each of the three overlaps. But the lateral joints would present a difficulty if the plates or sheets were of uniform length, since, in that case, the intersection of a lateral and terminal joint would involve the superposition of the corners of four sheets, which must be avoided by breaking joints in alternate courses. Hence a certain proportion of the sheets (easily determined by the circumstances of the case) should be ordered of extra length and an equal number of inferior length. In the case supposed of a 27 ft. rafter, one 8 ft. and one 6 ft. plate should be ordered for every six plates of 7 ft. The junction at the ridge is best effected by a cast-iron covering, sloping in both directions for a few inches, and with its edges corrugated to fit the surfaces of the plates, and overlapping them a few inches. This casting should be made of the best iron in the most accurate manner and of the least thickness consistent with sound casting. Openings for ventilators may be left in them if desirable. The plates should be prepared, before laying them, with a good coating of mineral paint, in which oxide of iron is a principal constituent.

We introduce a portion of an article by Mr. J. J. Birckel, published in the London "Artizan," upon the accidental stresses to which a roof may be subjected. "Among the accidental sources of pressure, wind and snow form the most important items, because both may occur simultaneously. According to General Morin's observations, snow may accumulate to the depth of 20 in., and as its weight is $\frac{1}{10}$th that of water, the pressure due to this element would be about 11 lbs. per square ft. The same philosopher, however, thinks that one-half this amount will make ample provision. We will keep on the safe side, and suppose it to be 6 lbs. per square ft. Respecting the wind, we subjoin a short table of the pressures produced at various speeds upon a plane of resistance supposed to be at right angles with the direction of the wind:

Speed in ft. per second.	Pressure per sq. ft.	Speed in ft. per second.	Pressure per sq. ft.
ft. in.		ft. in.	
10 0	0.2	46 0	4.7
13 9	0.6	65 7	9.6
26 3	1.5	131 0	38.4
35 7	2.8		

General Morin, from whose work the above data are quoted, thinks that a direct pressure of 3 lbs. per square ft. is quite sufficient to reckon upon; but English engineers differ from him on this point, and make allowance for a pressure of 7 or 8 lbs. per ft." [In this country, where tornadoes are not unfrequent, this allowance should be still greater, though the chief danger to be apprehended from such disasters is the access of the wind to the underside of the roof, through windows and elsewhere.] "In the following tables we give the items of permanent pressure due to the covering, and to the structure of the roof itself, which, added to the items previously defined, will make up the whole weight, which must form the basis of calculation of the strength of the roof:

Nature of Covering.	Weight in lbs. per sq. ft.
Common tiles	13
Hollow tiles	16 to 18
Slates	8
Rolled copper	3
Zinc	2
Galvanized sheet iron	2
Corrugated sheet iron	$2\frac{1}{2}$
Asphalte	$5\frac{1}{4}$

Table of Weights of Principals and Purlins.

Distance between principals	Span.	Weight of principal.	Weight of purlins for one bay.	Weight per sq. ft. of roof'g.
ft. in.	ft. in.	lbs.	lbs.	lbs.
6 6	26 0	137	225	2.03
6 6	40 0	337	290	2.20
6 6	65 9	888	418	2.87
6 6	82 0	1,668	482	3.80
9 10	26 0	194	508	2.59
9 10	40 0	502	653	2.76
9 10	65 9	1,387	943	3.39
9 10	82 0	2,625	1,088	4.34
13 1	26 0	245	959	3.33
13 1	40 0	580	1,233	3.26
13 1	65 9	1,705	1,781	3.81
13 1	82 0	2,755	2,055	4.22

Mean weight per sq. ft. 3.22 lbs.

Observations.—These data are quoted from Gen. Morin's work; principals supposed to be trussed as per diagram No. 2; their weight has been increased by the amount of one-fourth for deficiency in rafters; angle of roof about 25°.

If, now, we sum up the pressures arising from the various sources enumerated, we shall find that the loads per square foot, for different kinds of covering, are as follows:

Nature of Covering.	Weight in lbs. per sq. ft.
Common tiles	33
Hollow tiles	29
Slates	28
Rolled copper	23
Zinc	22
Galvanized sheet iron	22
Corrugated sheet iron	$22\frac{1}{2}$
Asphalte	$27\frac{1}{4}$

The load of 40 lbs. per sq. ft., which is generally taken by English engineers as a basis in the calculation of roofs, is by no means exaggerated, though it may be quite sufficient.

Aero-Steam Engines.—Some interesting trials of Warsop's air and steam engine have been for some time in progress at Nottingham; and the report upon the results has been made by a well-known and, in such matters, very painstaking London engineer. The engine, being started by steam in the ordinary manner, a single-acting air pump, worked from the crank-shaft, compresses air to a little more than the boiler pressure, the air thus passing through a long circuit of straight and coiled pipe, which traverses the exhaust pipe, makes several spiral coils in the chimney, then descends at one side of the firebox, exposed to the full fire, and finally connects with a valve-box, through which the air, more or less heated, enters the boiler at the bottom of the water space. So far as the experiments—carefully made upon an imperfect engine, worked alternately with steam alone and with steam and air—can be taken as establishing a principle, they indicate a considerable economy—an economy, however, beyond anything which, as yet, is inferable from theory. Further experiments upon a new and greately improved engine on Warsop's system are arranged to take place very shortly, when the results will be laid before our readers.—*Engineering.*

REMARKABLE ENDURANCE OF BESSEMER STEEL AXLES.

The following table gives in detail, the tests of several steel axles, taken at random from a number of axles made by the Pennsylvania Steel Company, out of their regular product of Bessemer steel.

The first test shows, probably, the most remarkable endurance on record, viz: bending backward and forward under a ton drop falling forty-six times from a height of $16\frac{1}{2}$ feet, and twelve times from a height of 18 feet, the axle being reversed after each blow, and the total deflection back and forth being 163 inches.

TESTS OF BESSEMER STEEL AXLES *made at the Pennsylvania Steel Works, Baldwin, near Harrisburgh, Pa., May,* 1869.

[Weight of drop 2,000 lbs. V shaped wrought iron tup. Bearings 3 feet apart on cast iron supports.]

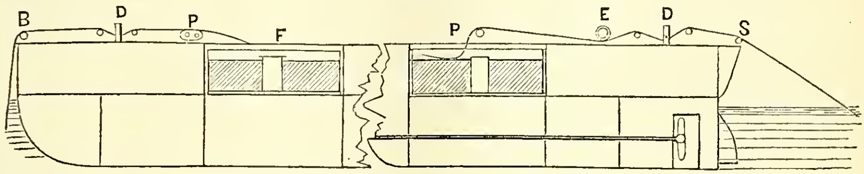
THE FRENCH ATLANTIC CABLE.

From "The Engineer."

In another column will be found a summary of a very interesting lecture by Mr. Fleeming Jenkin, one of the electricians engaged in the new Atlantic cable expedition, containing much information about the method of laying the French cable. We are indebted to Mr. Jenkin for the accompanying diagrams, which show some of the essential points of the appliances to be used to submerge the cable. Fig. 1 is a section of the Great Eastern, showing the tanks containing the cable, and the position of the paying-out and picking-up machinery; B is the bow-wheel over which the cable is hauled in; D the dynamometer; P the picking-up wheel; and F the fore-tank. The main tank is omitted; P aft-tank; E paying-out drum; D the dynamometer, and S the stern wheel, with the cable running out into the ocean.

Fig. 1.



Figs. 2 and 3 represent the most important part of the paying-out machinery, invented by the late Mr. Appold. Fig. 2 shows the principle of Appold's brake. In this cut O is the pivot of the break-wheel, and C the pivot on which the lever C, A, B works. W is the weight on the brake. The brake-wheel is attached to the paying-out drum. When the friction of the brake strap is greater than the weight W, the latter is lifted up, and as C, A, B is shorter than O, A, B, the change of angle relaxes the brake strap, and lets the wheel slip. In this way the strain on the cable never can exceed that of the weight W. Fig. 3 shows Appold's brake drum. In this cut C is the center on which the lever hangs, to which the weight W is attached, and applies pressure to the strap on the break wheel of the paying out drum. To prevent the weight W from vibrating, there is a piston at P, fitting closely into a cylinder containing water. T is a capstan wheel for lifting up the weight W when the paying-out machinery is entirely released from the brake.

Fig. 2.

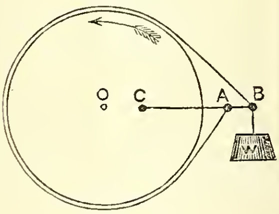


Fig. 4 shows the picking-up catenaries. In the upper part of the cut, M represents the grapnel at the surface of the water, showing the catenary which would be formed by a cable paid out with 14 per cent of slack and lifted in a depth of 2,000 fathoms. In the lower part of the cut, S represents the Great Eastern, and B, M, two auxiliary vessels simultaneously lifting the cable. M is a sharp grapnel intended to cut the cable, and so reduce the strain upon the cable at S.

Fig. 3.

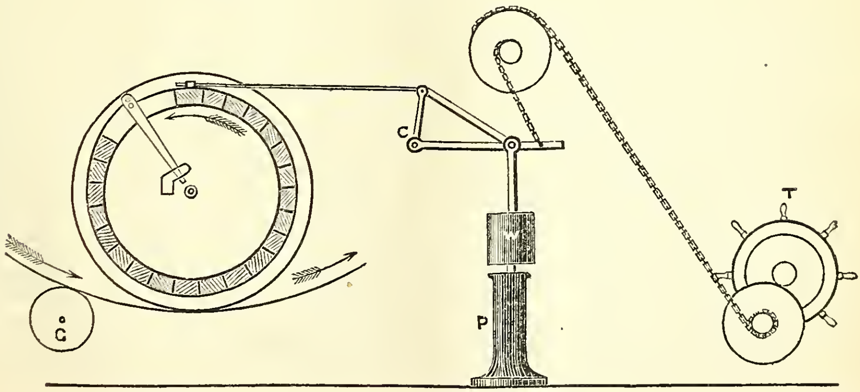

Fig. 4.

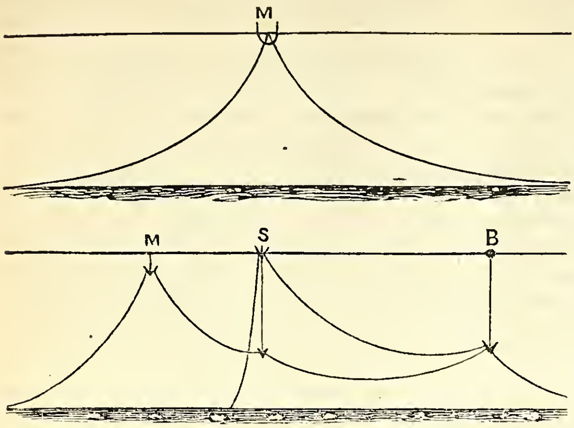

Fig. 5, representing the paying out of the cable, shows the angle at which the cable lies behind the ship in paying out at four knots per hour. E is the Great Eastern, and A the point where the cable reaches the bottom of the ocean, the practical depth of the water being 2,000 fathoms.

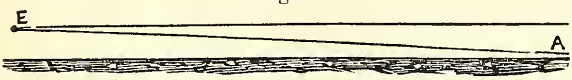
The shore ends of the French-Atlantic

Fig. 5.



cable are very heavy, but taper as they reach the deep sea portions. They have the same core as the main cable, and at the end furthest from the shore are each covered with twelve BB galvanized iron wires, .238 in. in diameter, weighing not less than 11,160 lbs. per knot. The heavy shore end next the landing places is first covered with twelve BB galvanized iron wires, nineteen inches in diameter, served with a sufficient quantity of tarred yarn to form a bedding for twelve strands, each formed of three galvanized iron wires .230 inches in diameter, giving a total weight of iron per knot of not less than 38,000 lbs. All the iron wire is of the quality known as "best best," free from inequalities, galvanized, annealed, and capable of being bent round itself and unbent without breaking. There is no weld or joint in any of the iron wires within twelve feet of any other weld. The shore ends are further covered, outside the iron wires, with two coatings of mineral pitch and silica, in the proportions of sixty and forty parts respectively, with sufficient mineral tar to give the requisite consistence, and with two servings of tar hemp yarn, laid alternately, the first coating of yarn being next the wires, then a serving of compound, then the yarn again, and lastly compound. The compound was applied hot and the yarn was laid over immediately afterwards. The yarn is everywhere covered with the compound, so that the outsides of the shore ends are smooth and regular. There are 18 knots of the heaviest shore end, and 127 knots of the lightest shore end; very little of this heavy cable will be laid off the coast of France, but a great deal off St. Pierre. At each end of the deep sea cable there will be a taper a quarter of a mile long, joining it to the shore ends.

The joints in the iron wires are made by scarphing the ends, binding them with fine wires and soldering them, each wire being also served with the best Manilla or New Zealand hemp steeped in tar. The conductor consists of a strand of seven wires of annealed copper, with an electrical resistance per knot at a temperature of 75 deg. Fah. of not more than 3.25 British Association units. The interstices of the strand are completely filled up with Chatterton's compound. The gutta percha insulator is put on in four concentric layers of equal thickness, with a layer of Chatterton's compound between each layer of gutta percha. The electrical resistance of the insulator at 75 deg. Fah. is not less than 250 millions of British Association units after one minute's electrification. The finished core is capable of resisting the passage of water along the conductor, when a pressure of 600 lbs. per square inch is applied at one end of a specimen 6 in. long. Very great precautions have been taken by the manufacturers to prevent faulty joints, for it is at the joints that electrical leakage is most likely to occur. During all processes of manufacture the cable was kept as much as possible under water, and on board the Great Eastern the cable tanks are kept nearly full of water, so that the cable is completely covered.

The main cable from the island of St. Pierre to the United States. is 700 miles long, and will take a very indirect route, because of the inequalities and dangers presented by the bottom of the sea off the eastern coast of America. This cable being shorter and more easily recoverable in case of accident, is not of such good quality as contains a conducting strand of seven copper wires, weighing 107 lbs. per knot, and the insulator, of gutta-percha and Chatterton's compound, weighs 150 lbs. per knot. This core is served with tanned jute yarn, with a covering of ten BB galvanized wires, .165 in. in diameter, weighing about 4,254 lbs. per knot. It has an outer protection of hemp and asphalte, laid on in two coatings. The shore ends are of the same description as those connected with the main Atlantic cable; in all there are twenty-two knots of the heaviest shore end, and fifty-four knots of the lighter shore end to be used with the main cable connecting St. Pierre with the United States.

In accordance with the terms of the contract between the "Société du Cable Transatlantique Français, Limited," and the Telegraph Construction and Maintenance Company, Limited, the latter will receive in all £920,000 if they lay the whole line successfully, and it keeps in good working order for six months. But the greater portion of the above amount has already been paid to them. The following are the particulars:

First payment		£50,000
3,564 miles of cable at £164 per mile	£584,496	
On completion of manufacture,	504	
		585,000
Seven payments of £20,000 each, when each length of 500 miles was coiled on board		140,000
When the ship leaves Brest		35,000
On completion of the section between Brest and St Pierre (in fully paid shares)		80,000
On completion of the section between St. Pierre and the United States		10,000
Six months after the completion of the whole (in fully paid shares)		20,000
		£920,000

Directly the Great Eastern returns to England she will take fresh cable on board and start for India, to lay a line between Bombay and Suez.

STEEL CASTINGS.—Railway-wheels, anvil-dies, gearing, frogs, and many other heavy parts are now cast by Butcher and other steel makers, at much less than the cost of forgings, and with double the strength and nearly the smoothness of the best iron castings. From our extended experience with steel dies for steam hammers, and with steel gearing, we are prepared to express the belief that steel castings rank among the great economies of the day.

THE SUBMERSION AND RECOVERY OF SUBMARINE CABLES.

CONSTRUCTION OF THE FRENCH ATLANTIC CABLE.

From a paper read before the Royal Institution, by Professor FLEEMING JENKIN, F. R. S.

The speaker began by stating that his object was to explain the principles on which engineers had acted in laying and recovering submarine cables, rather than to exhibit the details of the machinery employed. The general construction of electrical cables was first described, and specimens were shown; especial attention being drawn to the deep sea French Atlantic cable, consisting of the following parts: A copper conductor, gutta-percha insulator, and jute serving, surrounded by ten wires of homogeneous iron, each served with five Manilla yarns saturated with tar.

TABLE I.

Construction of French Atlantic Cable—Deep Sea Section.

	Lbs. weight per knot.	Diameter in inches.	Breaking strain, lb.
Copper	400	.168	644
Gutta-percha	400	.463	...
Serving	234	.669	...
Homo. wires (10)	1,589	.100	950
Manilla strands (50)	1,091	....	550
Each served wire	268	.245	1,550
Cable	3,701	1.134	16,530
Weight of cable in air	1.652 tons per knot.		
" " water	.753 "		
Strength in tons	$7\frac{3}{8}$ tons.		

Table No. 1 gives the dimensions, weights and strengths of each of the component parts. The wire served with hemp will bear a greater weight than the sum of the weights borne separately by the wire and the strands; and, again, the ten served wires, when formed into a rope, bear a greater weight than the sum of the weights which each will bear. Moreover, while the homogeneous iron elongates less than one per cent before breaking, and the hemp elongates only .75 per cent, the two combined stretch 3 per cent. This paradoxical result is due to want of absolute uniformity in the strength of each part; when separate, each breaks at the weakest point; when combined, the weakest points seldom coincide; hence, the strength of the combination is the sum of the mean strengths of the parts, necessarily greater than the sum of the minimum strengths. The so-called spiral or helical form does not really render the cable elastic or liable to stretch, nor does it compress the the one to be laid across the Atlantic. It core inside the sheathing, as was shown by an experiment where the core was actually withdrawn without causing the collapse of the sheathing.

The manner of coiling the cable on board ship was explained by diagrams and models; it being shown that, in order to avoid putting a twist into the rope when taking it out of the hold, it was necessary to put a twist in when coiling it away. Bad coiling produces kinks or loops drawn tight, which are avoided by a cone filling the eye of the coil, and by rings or equivalent arrangements preventing the bight, as drawn out of the hold, from lashing out under the influence of centrifugal force.

The following table gives the dimensions and contents of the "Great Eastern" tanks as arranged for the Atlantic expedition. These tanks keep the cable under water on board ship to facilitate the electrical tests. They carry a weight of 5,000 tons in a bulk of 180,000 c. ft., the tanks not being filled quite to the top.

TABLE II.

	Diameter.	Depth.	Cable knots.
Fore tank......	51 ft. 6 in.	20 ft. 6 in.	728
Main tank......	75 ft. 0 in.	16 ft. 6 in.	1,100
After tank.....	58 ft. 0 in.	26 ft. 6 in.	912

Notwithstanding their enormous weight and size, these tanks occupy a very insignificant proportion of the whole bulk of the "Great Eastern."

Mr. C. W. Siemens has for light cables employed a sort of reel or drum on a turntable, with partial success, instead of the fixed tank and coil. From the tank the cable, when paid out, passes over a pulley and along a trough to the brake drum, the object of which is to restrain the free exit of the cable to such an extent as is desired. The cable is laid hold of by being passed several times round a drum, as a rope making fast a vessel may be seen to be passed round a bollard; the friction allows a slight strain at one end to prevent a very heavy pull at the other end from causing the rope to slip round the drum. The slight pull at what may be called the light end of the rope is given by a series of jockey pulleys which play the part of the hand when the rope is allowed to slip round a bollard, but, in paying out a cable the rope does not slip round a drum; the drum itself turns round restrained by a friction-band or belt.

It is essential that this restraining friction should be constant—a result obtained by the Appold brake, which was explained by models and diagrams. In this arrangement both ends of the brake strap are attached to one lever, in such a manner that when the drum begins to turn it tends to lift the lever and weight hanging to it, and as the lever is lifted it slackens the brake-strap until the difference of tension on the two ends of the strap is equal to the weight hanging on the lever. When this is the case, the lever is no longer lifted, but remains stationary with the strap, allowing the drum to turn, restrained by a constant friction equal to the weight on the lever. If the co-efficient of friction increases, the lever will be a little more lifted and the strap slackened; if the co-efficient of friction diminishes, the lever and weight will fall, tightening the strap; but in any case the retarding force will be simply equal to the weight.

From the brake-drum the rope dips under a weighted pulley, which rides, as it were, suspended on a V of taut cable; if the strain increases, the rope straightens and raises the pulley, if the strain diminishes, the weight and pulley fall; thus the height of the pulley indicates the strain. This instrument is called the dynamometer. Lastly, the rope passes over a pulley into the sea.

Having shown how the cable was treated, the speaker proceeded to show how the strains to be expected could be calculated. A cable paid out in air hangs in a catenarian curve, but in water lies in a straight line, and the strains in the two cases are wholly different. In air the rope meets with no sensible obstacle to its motion, either longitudinally or in a direction perpendicular to its own length; in water, on the contrary, each foot of a cable meets with an opposition to its motion perpendicular to its length, which we may call Q, and for the Atlantic cable

$$Q = .154\ v^2,$$

where v is the velocity of the cable normally to its own length in feet per second. Thus, as the cable weighs .2575 lbs. per ft., it cannot sink faster than the speed given by the equation

$$.2575 = .154\ v_1{}^2,$$

from which v_1, the settling velocity, is found to be 1.294 ft. per second, or .765 knot per hour. The result of this resistance to displacement is that the cable lies in a straight line, not in a catenary curve, supported, as it were, by an inclined plane of water constantly yielding at the velocity v_1. The inclination of the straight line depends on the velocity of the ship and on v_1 not being at all affected by the tension of the rope.

The angle ϕ at which the cable will lie may be calculated as follows: Let P be the resistance of the water to displacement by each foot of the cable of the weight ω when lying at the angle ϕ,

$$P = \omega \cos. \phi;$$

let v_{11} be the velocity at which the cable moves perpendicularly to itself,

$$v_{11} = v \sin. \phi,$$

where v is the velocity of the ship.

$$\text{Also } P = \omega \frac{v_{11}^2}{v_1^2};$$

$$\text{hence, } \cos. \phi = \frac{v_{11}^2}{v_1^2} = \frac{v^2 \sin.^2 \phi}{v_1^2},$$

$$\text{and } v_1 = \frac{v \sin. \phi}{\sqrt{\cos. \phi}}; \quad . \quad . \quad 1 \text{ deg.}$$

and, assuming that the resistance is proportional to the square of the velocity, we have $\omega = Q\, v_1^2$, and hence,

$$\frac{\omega}{Q} = \frac{v^2 \sin.^2 \phi}{\cos. \phi}, \text{ or}$$

$$\frac{\omega}{Q\, v^2} = \frac{\cos. \phi}{\sin.^2 \phi},$$

from which we have

$$\cos. \phi = \frac{\sqrt{\omega^2 + 4\, m^2} - \omega}{2\, m} \quad . \ 2 \text{ deg.}$$

where $m = Q\, v^2$.

From this formula, as indeed from common sense, it appears that the greater the value of Q and of v the smaller the inclination with the horizon. The rough Atlantic cable, when the ship was going at the speed of six knots per hour, lay at an angle of $6\frac{3}{4}$ deg., so that the inclined plane was seventeen miles long, and each foot of the cable took nearly three hours to reach the bottom.

The strain T at the top of the inclined plane, if there were no friction preventing the rope from slipping back along the plane, would be equal to the weight of a piece of cable hanging plumb from the surface of the water to the bottom, or

$$T = \omega\, x,$$

where ω is the weight per foot run of the cable and x is the depth in feet.

But there is a sensible friction which helps to relieve the strain precisely as when a chain is lying on a solid inclined plane; calling m_1 the co-efficient of friction in pounds per foot length of cable at the velocity v in feet per second, and assuming that $m_1 = Q_1\, v^2$, the experiment of the Atlantic cable showed that $Q_1 = .00504$ (this is equivalent to .81 cwt. per knot of cable when slack is paid out at the rate of one knot per hour). The result is, that when slack is paid out, say at the rate of one knot per hour, and when $\phi = 6.45$ deg., the strain is diminished by one-half, and if slack were paid out at the rate of 1.4 knot per hour, or $23\frac{1}{2}$ per cent, this particular cable would require no retarding force whatever.

The strain T_1, when the velocity of the cable is v_{111}, can be found from the following formula:

$$T_1 = \omega\, x - m_1 \frac{\left(\frac{v_{111}}{v} - \cos. \phi\right)^2}{\sin. \phi} x \ldots . 3 \text{ deg.}$$

Cables of light specific gravity have a small settling velocity and lie at great length in the water, and, if they are also rough, the co-efficient Q_1 may easily be so great as to relieve the brake of most of the strain which would be necessary to lay a cable of equal weight but small bulk and smoother surface, with the same amount of slack. If no slack were laid, there would be little difference between the tension required for cables of different construction but of equal weights in water. When much slack is laid, all cables will be considerably less strained than if laid without slack; and, finally, the faster the ship goes the less slack is required to produce any given amount of relief.

The correctness of the above theory has been amply proved in practice. If in seas 2 miles deep the cable hung in a catenary $12\frac{3}{4}$ miles long, the weight to be carried would be $8\frac{1}{2}$ tons, and the strain on the cable 29 tons; while, if the cable hung in a catenary the inclination of which to the horizon at the stern was 9 deg. 30 min., the length would be 24 miles, the weight 17 tons, and the strain 102 tons instead of about 14 cwt.—the strain actually observed for the Atlantic cable when being paid out at 7 knots per hour while the ship was going at 6 knots per hour. The rise and fall of the ship, even in heavy weather, very slightly affects the strain while paying out, on account of the slight inclination of the cable to the horizon. The margin of strength in deep sea cables of the Atlantic type is even greater than is given in most engineering works, since the cable will bear tenfold the strain which is found necessary in laying.

The process of grappling was next described, and the operation illustrated, by dragging a miniature grapnel over the floor, so as to hook a chain lying there. When the cable is hooked, the strains of the grapnel rope are simply the weights of the bight lifted, and the length of this bight depends on the slack. Thus, with 14 per cent of slack, the length of the cable lifted will be 4.89 times the depth to which it is raised. Thus, in two miles of water, about 9.8 miles of cable will be lifted, the weight on the grapnel will be 6.86 tons, but the strain on the cable will be only one component of this weight resolved in the direction of the tangent to the curve at the grapnel; this strain will be 5.5 tons. Thus, it is clear, that in calm weather, with 14 per cent slack, the cable can be lifted from a depth of two miles. This was actually done upon one occasion; but owing to the pitching of the ship the cable parted, and we successfully recovered by the obvious device of grappling the cable in two points about $2\frac{1}{2}$ knots apart, and breaking the cable at the point furthest from land; the loose end then hung down over the other grapnel, and it is obvious that by this plan the strain on any cable in any depth can be limited to the simple weight of a length of cable hanging from the surface to the bottom. The Atlantic cables will bear five times the strain due in this manner to two miles of depth, and for this operation the margin of strength is also ample. The cable is hauled in by machinery very similar to that adopted for paying out; the drum being simply turned in the opposite direction by a steam engine, if only a small length is to be picked up. If many miles are required, the cable is transferred to the bow, and hauled up by a double drum to avoid the fleeting necessity on a single drum. The friction on the water during the operation adds to the strain; thus, with the valve of Q_1 previously found, at one mile per hour, the friction per mile would be .81 cwt., adding in a depth of two miles 1.61 cwt. to the strain due to the simple weight; besides this, there is some resistance due to the displacement of the water, by the bight of the rope at the bottom, and some extra weight due to the fact, that the cable hangs in a catenary, not in a straight line. The length of this catenary depends on the rate at which this cable is hauled through the water; but even after allowing for all these things the strength of the cable is from three to four times greater than the strain which, in fair weather, need come on the cable when being picked up from a depth of two miles—a margin of strength not unfrequently adopted even in permanent engineering works.

It was by calculations like these, that before the 1865 cable had been recovered in 1866, the speaker was able to write in "The Times," of August, 1865, "If the cable retain its strength, as it probably will, it can certainly be raised;" and now that experience has confirmed theory, engineers are justified in looking forward with great confidence to the continued prosperity and extension of deep-sea telegraphy. The following tables give some further information as to the French Atlantic cable about to be laid, which will cover fifty acres of ground, being a narrow strip, 3,564 knots long, and a little more than an inch wide.

TABLE III.

Lengths and Weights of Materials used in French Atlantic Cable.

	Knots.	Tons.
Copper wire	24,948	533
Gutta-percha	3,564	549
Jute serving	......	500
Homo. wire	27,222	1,872

THE MAST HOPE DISASTER.—Nearly every railway disaster can be traced to bad or worn-out plant and machinery. But after all the modern refinements of materials and construction have been applied, there come to us, about twice a year, the ghastly details of a wholesale murder by the very refinement of stupidity. A misplaced switch, the absence of a signal behind a stopped train, running into a drawbridge, and, sublimest of all, colliding with a train supposed to be on a siding; this is manslaughter, and must be punished as such. No hidden defects in materials or construction can excuse it.

WHEEL-BASE OF RAILWAY VEHICLES—SAFETY OF THE AMERICAN TRUCK.

Although the practice with our common "spread" truck has been remarkably successful, there appears to be something for English engineers to say on the other side of the question, for instance, the following, from a correspondent of "The Engineer," with reference to an article on railway safety which we have quoted from that journal on another page.

The bogie is, in fact, a means of reducing the wheel-base without reducing the length of carriage-body; and the object of this reduction of wheel-base is to diminish that obliquity of the axles which results from their fixed parallelism. This obliquity, in the case of a four-wheeled truck standing centrally between the rails, is well known to be directly proportional to the length of wheel-base, and the conclusion appears to have been jumped at that the shorter the wheel-base the less the obliquity. But the consideration seems to have been overlooked that this obliquity is liable to an increase from the turning of the truck about the bogie-pin until the diagonally opposite wheels touch the rails with their flanges, and that the angle through which the truck can thus turn is *inversely* proportioned to the wheel-base. It is true that while this increases the obliquity of one axle, it diminishes that of the other; but this is no abatement of the damage, since it is the greatest obliquity of any axle that measures the tendency of the truck to leave the rails or burst the track. And this turning of the truck about the bogie-pin, if it be not brought about by chance oscillations, producing the wriggling or "wobbling" which you describe, is certain to be pushed to its extreme limit in one direction, during the passage of curves, by the action of a couple resulting from the resistance of the wheels to being slipped or skidded as they must be to compensate for the inequality of their paths. Now in English stock coupled tightly together, not only are the chance oscillations checked and absorbed by opposing the mass of one carriage to the impetus of its neighbor, but the couple above referred to is neutralized by the action of the same couple in the next carriage; while the American bogie, free of all restraints, is left to wriggle and wobble at its own sweet will.

Leaving this out of account, however, and considering that the possible angle of obliquity of the leading axle is, as above stated, the sum of two angles, of which one is directly and the other indirectly proportional to the length of wheel-base, it is clear that a truck may have too short as well as too long a wheel-base for the safe transit of a given bit of road, and that *there is a length of wheel-base which will give a less obliquity of axle than any other, shorter or longer.* The determination of this length and the calculation of the angle of obliquity for any given case is a simple matter; and it will be easy to demonstrate that there are circumstances of common occurrence under which an ordinary English carriage will traverse a sharp curve with less obliquity of axle than an American bogie.

Thus, the sine of the angle of obliquity caused by parallelism of axles is $= \frac{l}{2r}$, l being the length of wheel-base and r the radius of curve; and as the angles will in any case be small, we may say that this is approximately = the circular measure of the angle. The circular measure of the angle through which the truck can turn in either direction is approximately $= \frac{s}{l}$, s being the play of the flanges, i. e., gauge of rails minus gauge of wheels outside flanges. Thus the obliquity of axle $= \frac{l}{2r} + \frac{l}{s}$.

And the length which will give the smallest angle of obliquity is $= \sqrt{2r\,s}$

Now let us take a 10-chain curve for example; and as the gauge is sure to be widened on such a curve, and we have to take the *worst case*, it will not be too much to assume that s may be = 1 in. Then using the above formulæ, we find that the best length of wheel-base, or that which gives the least obliquity of axle in this case is about 10 ft. 6 in. (an ordinary English carriage), while *an American bogie of 5 ft. wheel-base would actually present its leading axle at as great an angle of obliquity as a carriage with 22 ft. wheel-base.* On flatter curves, supposing the play to remain the same, the disadvantage of the short wheel-base is even more apparent.

The conclusion to which we are driven, then, is that though on sharp curves a long wheel-base is dangerous, yet the difficulty is not to be obviated by shortening it, because of the unsteadiness thereby induced; and the only satisfactory solution of the problem will be by some simple arrangement by which the wheel-base may be maintained of any desired length, and the axles truly radiated to the curve.

VELOCIPEDES.

From "Engineering."

We have for a long time excluded the subject of velocipedes, as one of diminutive carriage building, from the pages of "Engineering"; but they have in the mean time become articles of extensive manufacture by large and long established firms of mechanical engineers, railway carriage builders, and others. In Birmingham, for example, at least three eminent firms are engaged in making, by scores, if not by hundreds, what, a year or two ago, were thought to be little better worthy the attention of engineers than Bath chairs or perambulators. The principal of a velocipede—and with all their alleged differences velocipedes are much alike—is a little paradoxical to those who consider it for the first time. How is it that they can stand upright on two wheels only, one trailing behind the other? And how is it that the rider can accomplish fifty miles as easily, if not easier, than eight or ten miles of walking? As to the first question, the principle is the same as that which keeps a boy's hoop upright as long as it is kept in rotation, the tendency of all revolving bodies to continue in revolution in the same plane as that in which they were first made to revolve. With internal propelling mechanism, a velocipede might run by itself, the rider, who once puts it into motion, has only to preserve his own balance, and not that of the machine *per se*, which, once equilibrated on both sides when at rest, will take care of itself when in motion.

As to the reason why there is less fatigue in working a velocipede than in walking, a little examination is necessary. Whatever the weight of the velocipede and rider, it is a rolling weight only, and the resistance to rolling, at, say, ten miles an hour, will not much exceed one-fortieth of the weight when this is moved over a smooth, level road. Taking the total weight as 210 lbs., or, say, 15 stone, the rolling resistance would be but $5\frac{1}{4}$ lbs., and as a muscular man can easily, for an hour or more, and under the exhilarating influence of a race, work up to at least 4,620 foot-pounds per minute, this would correspond to an advance of 880 ft. per minute, or ten miles an hour. The late Mr. Glynn's work on cranes quotes instances of a much greater exertion of human strength for short intervals, in some cases nearly 30,000 foot-pounds per minute, or much above the average power exerted by an ordinary horse, and nearly equal to the standard horse power of the engineer. The writer himself, weighing 180 lbs., has often raced up a circular staircase of fifty-six steps, and rising 32 ft. 6 in., in thirteen seconds. Were this rate continued (not that he could so long continue it) for even a minute, it would correspond to the exertion of 27,000 foot-pounds in that time. One-sixth of this work, or 4,500 foot-pounds per minute might, probably, be continued for a considerable time, and this would carry him and his velocipede at nine or ten miles an hour on a good level road. The force would be exerted in the latter as in the former case by the great extensor muscles of the legs, the weight of the body being wholly carried on the velocipede, instead of being lifted as on the staircase.

In walking, muscular strength is expended in alternately lifting, by either leg, its fellow leg, and the weight of the whole body above both legs, through a distance, at each step, corresponding (were there no "spring" to the feet) to the rise of the arc described by the body in swinging over either leg upon a fixed unyielding fulcrum at the foot. The beautiful mechanism of the foot, of itself, takes off a good part of this lift, but neither the head nor any portion of the body advances in a truly horizontal line when walking, this being the case only in rolling along a level plane. There is, too, the irregularity of advance of the body, which is accelerated and retarded at each step to give time to "change legs," and there is the power expended in moving the legs themselves, considered as weights, to be stopped and started at every step. In this way, together with the strain imposed upon the muscles of the legs in the mere statical support of the body, as much fatigue may be occasioned in an hour's walk of three miles as in a spin on a velocipede at three or four times the speed.

And the bicyclical contrivances appear to possess a commercial value in their use. At any rate we hear of a firm of mechanical engineers who assert that they save 40s. weekly on an average, in cab fares, messengers, &c., by retaining a sharp velocipedestrian as a means of communicating between their two establishments, less than half a mile apart, a private telegraph being unavailable for the transmission of drawings, parcels, samples, daily accounts, &c.

TRANSMITTING POWER BY ROPES.

From "Belting Facts and Figures," by J. H. Cooper, in the "Journal of the Franklin Institute."

Among the more recent improvements in the way of *transmitting power* for long distances, is the substitution of belts by endless wire ropes, running at a high speed; their use bids fair to add immensely to our manufacturing facilities. The distance to which you can thus transfer power ranges from 75 ft. to 4 miles. Just where the belt becomes too long for economy, there the rope steps in. In place of a flat faced pulley, a narrow sheave with a deep flaring groove is used, the groove being filled out, or lined rather, with leather, oakum, india rubber, or some other soft substance, to save the rope. The essential points are a large sheave, running at a considerable velocity, and a light rope. When the distance exceeds 400 ft., a double grooved wheel is used, and a second endless rope transmits the power 400 ft. further, and so on indefinitely. The loss by friction is about 8 per cent per mile. A few examples may prove of interest, and give information.

It is required to transmit 300 horse-power by means of a wire rope. A wheel $14\frac{1}{2}$ ft. diameter, making 108 revolutions per min., is sufficient; the rope running at a rate of 4,920 ft. per minute—size of rope required, one inch diameter. The distance has nothing to do with it. Again: "It is desired to transmit for any distance as much power as a 12 in. belt will give." Assuming that the belt travels in the neighborhood of 1,300 ft. per minute, it is about equivalent to 20 horse-power, and a grooved sheave of 7 ft. diameter, running 100 revolutions per min., with a $\frac{5}{8}$ in. rope, will be the proportions required. Again, a 4 ft. wheel, running 100 revolutions per minute, with a $\frac{3}{8}$ in. rope, will convey from 4 to 5 horse-power. The cost of the rope is always the smallest item, amounting to a few cents per foot, and not one-tenth the cost of an equivalent amount of belting. One is thus enabled, at a small expense, to transmit power in any direction; for instance, to a building lying remote from the main factory buildings, where it is not worth while to put up a separate engine. Across rivers, creeks, canals, streets, over the tops of houses, under water, from cellar to roof, etc.

Frequently an excellent site for water power remains unimproved for want of suitable building sites in the neighborhood. The water may be conveyed *down stream* by means of expensive canals and flumes; but by a wire rope transmission we can transfer it in any direction, either up stream, across it, or sidewise, up and down grades of one in eight—in fact, anywhere. "In many sections of our country coal is dear and water power plenty, but not improved, for reasons which may be set aside by the above method. In Europe over a thousand factories are driven in that way."—*The Manufacturer and Builder*, Feb. '69, p. 38.

In a paper by Mr. John Ramsbottom, in "Newton's Journal," vol. XXI, p. 46, on traversing cranes at Crewe Locomotive Works, dated January 28, 1864, mention is made of the means by which power is communicated from the shop lines of shafting to the gear of the cranes. It consists of a $\frac{5}{8}$ in. diameter soft, white cotton cord, weighing about $1\frac{1}{2}$ ounces to the foot, running at the rate of 5,000 ft. per minute, in a line with the longitudinal motion of the crane, above the same and over a 4 ft. diam. tightener sheave. This sheave is weighed so as to put a tension on each strand of the cord of 108 pounds, which is found to be the best working strain for keeping the rope steady, and giving the required "hold" on the main driving pulley. The cranes have a span of 40 ft. 7 in., a longitudinal traverse of 270 ft., and the rails are 16 ft. above the floor. The cord is supported every 12 or 14 ft. by cast iron fixed slippers of plain cross section, $1\frac{5}{8}$ in. wide, with side flanges. These slippers are placed $1\frac{1}{2}$ in. below the working line of the driving side of the cord, so as to allow the driving wheels on the traverser to pass them; they are not oiled, and the friction of the cord in them amounts to two-fifths of the working load.

Motion is communicated to the gear of the crane by pressing the cord into grooved cast iron pulleys. The grooves in the driving pulleys are V shaped, at an angle of 30°, and the cord does not touch bottom; the guide pulleys have circular grooves, same diameter as the cord, and the pressure pulleys have a circular groove of larger diameter than the cord. The driving pulleys have a diameter equal to thirty times the diameter of the rope. Guards are put on the pulleys to keep the ropes in. The driving power of the cord to lift 25 tons is only 18 pounds, irrespective of friction, which is a ratio of 3111 : 1. Light loads are about 800 : 1. In the gib cranes, driven by similar means, the ratio is 1000 : 1 when lifting 4 tons at the rate of 5 ft. $1\frac{1}{2}$ in. per minute. The actual power required to lift 9 tons, besides the snatch block and chain, has been found to be 17 pounds at the circumference of the driving pulley. The crab, when unloaded, requires $1\frac{1}{8}$ pounds to overcome its friction. The cords are soon reduced to $\frac{9}{16}$ in. diameter, and last about eight months at constant work. In an overhead traverser, used in the boiler shop, lifting six tons, three years in use, a $\frac{5}{8}$ in. cord was employed, but was afterwards changed for a cord $\frac{1}{2}$ in. in diameter. The light driving cord is the only plan compatible with high speeds; a heavy chain, belt or cord, would soon wear out and break by its own weight.

THE CENTRAL RAIL.

From "The Engineer."

The really successful thing, and perhaps the only complete success, on the Mont Cenis Railway is the central rail. Without even stating that the central rail is absolutely required, if we merely consider the tractive force required on the Mont Cenis, it seems to us to be the most important innovation in locomotive work that has been made during the last twenty years. It is the only means yet discovered of obtaining adhesion without increasing weight, or without that adhesion being dependent on weight for its existence. Apart from the plan of applying powerful electro-magnets to the wheels, which has not been found to answer, though tried more than once; and the fixed rope scheme of Mr. David Greig—avowedly only a substitution for the central rail—the central rail constitutes the only system yet conceived for working a locomotive independently of the adhesion obtained by its weight. It is remarkable how difficult locomotive engineers, even of great ability, find it to disconnect in their minds great tractive power with the rail-adhesion produced by the actual weight of the engine bearing on the driving and coupled wheels. With ourselves it has always seemed a mechanical absurdity to provide weight in order to get the power to lift it up and carry it along. With all the wheels coupled together the maximum obtainable adhesion is obtained; but there is practically no limit to the amount to which the horizontal wheels in the Fell engine can be brought to clip the central rail. The central rail again offers a comparatively immense amount of security against running off the line, and an admirably speedy and safe means of braking the train on a descent. Certainly, when looking down the precipices passed by the Fell trains, without the knowledge of the use of the central rail we should scarcely have felt unconcerned and comfortable. The force of the wind also on these mountain passes is sometimes so tremendous that the extra protection and hold afforded by a central rail is an absolute necessity.

Working with a central rail has more than once been proposed during the last forty years; but in great improvements, not merely the man, but also the hour, must come together. Vignoles and Ericsson patented in 1830 the central rail with very different motives and views to Fell, and certainly not with the intention of getting an engine and train over such sharp curves and steep inclines as those on the Mont Cenis. An American engineer, however, not merely patented the plan in England, but actually carried it out for a short time in America, though he afterwards dropped it, proving that he had not that faith in the plan which he might have had if he had fully understood its importance.

It would not be fair to compare the central rail with schemes which have never been tried. The heavy Engerth engines on the Semmering have scarcely been a success, either in themselves or in their effects on the permanent way. What is the result of some of the very best practice in the kingdom when seeking to obtain greater adhesion from actual weight? On the Metropolitan Railway, engines weighing about forty-two tons have to be employed to draw trains weighing about eighty tons. In this there seems to be a sort of mechanical contradiction of terms. Mr. Fell's engines have been stated by Mr. Brunlees to weigh only sixteen tons, and putting twenty-four tons pressure on the horizontal wheels, plus the weight of the engine itself, the co-efficient of adhesion of one-fifth gives a total adhesion of one-half the weight of the engine. It must also be borne in mind that when people speak of getting on an ordinary line of rail an adhesion of one-fifth, or even more, of the load, they tacitly assume the rails to be in good condition. With rails in bad condition it is believed by engineers of the highest standing that whatever may be the weight of the engine, the wheels are liable to slip. There is also special reason on this line why, apart from other causes, an extra amount of adhesion is required. It appears that on the Mont Cenis a fine dust of a most lubricative nature is blown down upon the rails in dry summer weather. This is the dust of the schistose rock of which the road—which is still partly used for ordinary traffic—is mended, and when wetted besides, the rails are sometimes in a worse condition for adhesion than from the snow in winter.

It is not perhaps impossible that such light loads as those now taken up Mont Cenis could be taken without the central rail; and certainly this might be done *if* the line were straighter—but whether with as much safety is another and a very different question. Suppose, then, we assume it as proved that the adhesion produced by weight alone would carry a remunerative load up a gradient of 1 in 10 or 12, how about passing such sharp curves as there are on the Mont Cenis? In the first place, the central rail diminishes the friction in passing round very sharp curves; and the wonder is even witnessed on the Mont Cenis that sharp curves are passed more easily than the straight line in an ordinary line, the resistance to traction on a curve of only 400 ft. radius has been estimated as *double* the resistance on a straight line on a level. And there has been no instance of an engine running off this line—no small advantage with a precipice on one side of you thousands of feet deep.

In fact, the wonder in passing the Mont Cenis is not so much at the tractive power of the engine—as the load is but slight—but the ease with which the train winds its way over a serpentine road, passing over curves of little more than five or ten chains radius. The horizontal gripping wheels of the engine, and the horizontal guide-wheels of the carriages, keep the train true on the line, and prevent much of the usual prejudicial action from coming into play. Just as the adhesion is practically unlimited, so is the brake power in descending the steep gradients. On such a difficult line as an Alpine line—whereon, in winter, guards have to be placed to warn as to descending avalanches—the ease whereby a train can be stopped is of the greatest necessity. We think that very few disinterested people can come to any other conclusion than that, on such lines, with such complicated conditions, differing so much from our own, the central rail system is the only one to be depended upon for tractive and brake power, flexibility round the curves, safety to life, and practicable cheapness. It seems to us not impossible that we should have an approach to perfection in a sort of combination of the engines advocated by M. Thouvenot and Mr. Fairlie with the central rail. Of these two tank-engines, placed back to back—united as to their fire-boxes and boilers—one pair of cylinders could work the four coupled wheels of one bogie-frame in the ordinary way, and the other pair could be set to work the gripping wheels on Fell's plan on the second frame. With such a combination there need scarcely be a single piece of gear more than if only vertical driving wheels were used.

Goods Engines for Steep Inclines.—The Paris, Lyons and Mediterranean Railway Company will work the steep inclines of the new branches now in progress with eight coupled engines of a new pattern. Twelve engines of this system are being manufactured at the Graffenstaden Works, at the price of £52 8s. 3d. per ton, but the working drawings were prepared in the offices and by the engineers of the company. These engines have fire boxes overhanging the rear drivers, and outside cylinders. The valve gear is also outside, the eccentrics being supported by an overhang to the end of the crank pin of the driving axle. The frames are curved transversely to clear the fire box, which is of unusual width. The curved part of the frame is strengthened by a strong wrought iron bracket, a contrivance which has been used with much success by the Eastern Railway. The first and fourth axle have an end play of 1 in. in the brasses, and spherical crank pins for the coupling rods, enabling the engines to pass easily round curves 720 ft. radius; all the wheels are, of course, flanged. The engine is suspended by eight springs and four compensating beams. The boiler is fed by a single injector, connected through two india rubber pipes to a tender, which has nothing worth noticing, and weighs about twenty tons in working order. The engines, as well as all the other engines of the company, are fitted with the Lechatelier reversing arrangement, and Thierry's smoke-consuming apparatus. The following dimensions of the most important parts of these engines are from "The Engineer."

Fire grate.

	ft.	in.
Length	5	1
Width....................	4	$5\frac{1}{5}$
Surface in square feet	$12\frac{1}{3}$	

Inside fire box.

	ft.	in.
Height next the tube plate.....	5	$10\frac{1}{5}$
Height next the door	5	$4\frac{2}{5}$
Inside width at the top...	4	$2\frac{4}{5}$
Inside width at the bottom	4	$5\frac{1}{5}$
Inside length at the top........	4	$6\frac{4}{5}$
Inside length at the bottom	5	1

Thickness of fire box, copper.

	ft.	in.
Door plate		$\frac{3}{5}$
Side plate...................		$\frac{3}{5}$
Top of tube plate		1
Bottom of tube plate..........		$\frac{3}{5}$

Tubes.

	ft.	in.
Number 244		
Outside diameter		2
Length	17	7
Heating surface of fire box (sq. feet).....................106		
Heating surface of tubes in sq. feet.....................2,132		
Total heating surface in sq. ft., 2,238		

Outside fire box.

	ft.	in.
Length at the top	5	$3\frac{4}{5}$
Length at the bottom	5	$7\frac{4}{5}$
Width	5	$0\frac{3}{5}$
Thickness		$\frac{16}{25}$

Boiler.

	ft.	in.
Diam. outside of smallest plate..	4	11
Length	17	3
Thickness		$\frac{16}{25}$
Height of the center above the rail	6	$6\frac{2}{5}$
Steam pressure ....125 lbs.		
Diameter of each safety valve ..		$5\frac{1}{5}$

Chimney.

	ft.	in.
Diameter....................	1	9
Height above the rail	14	4

Frames.

	ft.	in.
Inside distance at the front	3	$11\frac{3}{5}$
Inside distance at the back	5	$10\frac{1}{5}$
Thickness		$1\frac{1}{5}$
Total length of the engine.....	32	2

Wheels.

	ft.	in.
Diameter	4	$1\frac{3}{5}$
Distance of axles.............	4	$5\frac{1}{5}$
Total wheel base	13	$3\frac{3}{5}$

Miscellaneous.

	ft.	in.
3d axle		8
1st, 2d and 4th		$7\frac{1}{6}$
Length of journals............		10
Diameter of cylinders	1	$9\frac{1}{5}$
Stroke......................	2	2
Length of connecting rods	8	$4\frac{2}{3}$
Distance between centers of the cylinders..................	6	$13\frac{2}{5}$
Angle of advance of eccentrics, 35 deg.		
Throw of eccentrics		$2\frac{4}{5}$
Stroke of slide valve in full gear		$5\frac{3}{5}$
Inside lap of slide valves		$\frac{1}{50}$
Outside lap of slide valve......		$1\frac{1}{6}$
Average admission in full gear..		$\frac{4}{5}$
Length of steam and exhaust ports	1	$2\frac{1}{5}$
Width of steam ports		$1\frac{4}{5}$
Width of exhaust ports........		$3\frac{3}{5}$
Number of spring plates.......	11	0
Width		$3\frac{3}{5}$
Thickness.		$\frac{1}{2}$
Length	2	10
Camber		$3\frac{1}{5}$
Distance of center of gravity in front of 3d axle............	2	$0\frac{2}{3}$
Total weight of engine empty .. 43 tons.		

Distribution of weight in working order.

	tons.	cwt.
1st axle......................	12	0
2d axle	12	0
3d axle	12	13
4th axle	12	13
Total weight............ .	49	6

These engines are especially designed for working steep inclines at very small speed. A single engine will easily take, at ten miles an hour, a 200-ton train up an incline of 1 in 40, or better, two engines, one at the front and the other behind, will work a 400-ton train. With so small a speed the overhang of the fire box and the end play of the leading and trailing axle are without any practical inconvenience. The company do not intend, of course, to work their main lines with these engines, where the speed is much greater, and where the six-coupled engines now in use are quite sufficient.

British Heavy Guns.—In a recent article, the London "Times" drew attention to the comparative trials for endurance of 9-in. guns now in progress at Woolwich. It was stated that one pattern of the Woolwich coiled wrought-iron gun had endured 400 rounds with ordinary service charges of 30 lb. English large-grain cannon powder, and 714 rounds with battering charges of 43 lb.; in all, 1114 rounds—a test far beyond anything that such a gun could probably be called upon to resist even during a great war. The gun remains perfectly serviceable. The gun and its ammunition were calculated for each other, regard being had both to power, endurance, weight, and cost; and that there may be no mistake as to the powers of the Woolwich 9-in. gun, with battering charges of 43 lb., we give the maximum penetrations which the gun is capable of effecting, as laid down by the Committee on Fortifications: into earth 40 ft., into concrete 12 ft., into brickwork 12 ft., into rubble masonry 8 ft., into massive granite 2 ft. (but with fracturing and disintegrating effect to a much greater depth, and over a considerable area), into iron plating 11 in. Well-trained gun detachments can, if the circumstances are not unfavorable, load, aim, and fire the 9-in. gun at the rate of one round per minute, so that a six-gun battery could deliver a shot or shell well aimed every 10 seconds.

The difference between the second or ordinary pattern of the Woolwich gun and its predecessor under trial consists in certain details of construction. The first trial gun had a steel tube only 2 in. thick, the second a 3-in. tube. In the first the coils intended to form the breech of the gun were made up in two masses, so that the breech consisted of two layers of wrought iron over a thin steel tube. In the second the whole of the wrought iron covering the breech of the tube had been previously welded up into one mass, so that the breech consisted of one layer of welded coils over a thick steel tube. The result has been in favor of the gun with less steel and more iron disposed in two layers. The endurance of both pieces has been eminently satisfactory.

The second gun has fired 400 rounds with 30 lb. charges, and 649 with 43 lb. charges—1,049 rounds in all. During the firing of the 400 charges of 30 lbs. and during 207 of the 43 lb. charges, the vent was in rear of the usual place. The last 442 rounds with 43 lb. were fired through a vent in the ordinary service position, which is more severe upon the gun. The piece is now unserviceable, but became so by a most gradual and easily watched process. About 200 rounds before the end of the trial a flaw was detected in the steel tube. It developed gradually, though the steel barrel is tightly gripped by the wrought-iron exterior, up to the 1002nd round, when gas was discovered escaping from the indicator hole—a small orifice bored in all our heavy guns to give notice when a steel tube is cracked through. The proof was continued with full battering charges until, at the 1049th round, the steel tube shifted forward about 2 in. and closed the vent, so that further firing became impossible. Thus, though the gun is unserviceable, it has stood an enormous test, and yielded slowly at last, step by step. We need hardly say that no accident could possibly have happened to any one. Cases, very few and far between, might possibly occur of a Woolwich gun bursting at proof if the steel tube happens to be exceptionally bad, because the proof charge is inordinately large. We have known one such case. Indeed, the proof is intended to test thoroughly every part of a gun, not merely the interior. This trial was merely comparative; but, while it has shown the advantage of using thin interior steel tubes or barrels in preference to thicker ones, it has also shown that Woolwich guns, made on either pattern, are capable of an endurance entirely unknown among the expensive heavy guns possessed in extremely limited numbers by Continental powers.

TESTING STEAM ENGINES.

From "Engineering."

Although the ordinary method of expressing the performance of a steam engine by stating the number of pounds of coal per horse power per hour consumed in working it, no doubt possesses some points of practical convenience, yet as a means of comparing accurately the performances of different engines it is absolutely valueless. That this is the case will be readily admitted when it is considered that the number of pounds of coal consumed per horse power per hour by any given engine may be varied within very wide limits without the engine itself being modified in any way. Any given engine working at a given speed, under a constant load, and supplied with steam at a constant pressure, will, so long as no derangement of its parts takes place, consume a certain constant quantity of that steam per hour; but, on the other hand, the amount of fuel consumed in generating this quantity of steam may vary considerably according to the description and proportions of the boilers used, the quality of the coal burnt, the care and skill exercised in stoking, the means adopted to prevent loss of heat by radiation, and other details which it is unnecessary that we should mention here. It thus follows that a bad engine supplied with steam by an economical boiler worked by skillful stokers may, according to the ordinary method of estimating performance, show as good a result as an engine which is in reality very superior to it, but which draws its supply of steam from boilers of less efficient proportions, or less carefully fired than those of its rival, and this although the same quality of coal is used in the two instances. Even if the two engines are supplied with steam from boilers of the same class fired with equal care, the comparison is rarely a perfectly just one; for with all boilers there is a certain rate of evaporation at which the consumption of fuel per pound of water evaporated is less than at any other, and it may—and in practice probably always will—happen that the supply of steam needed by the one engine will approach more nearly to this rate of most economical evaporation than that required by the other, and hence an inequality of which it is impossible to estimate the amount with accuracy. The fault, in fact, of the ordinary system of estimating steam engine performance is that it considers the engine and boiler as a whole instead of regarding them as two entirely independent parts, either of which may be good or bad without in any way affecting the efficiency of the other.

A better measure of the efficiency of any given engine than the number of pounds of coal consumed per horse power per hour in supplying it with steam, is the weight of that steam as estimated from the quantity of water evaporated by the boiler. We say *estimated* advisedly, for there are but few boilers which do not prime to some greater or less extent, and the amount of this priming will, of course, always cause the apparent evaporation to be somewhat greater than that which actually takes place. The practice of estimating the efficiency of an engine by the quantity of water consumed by it, has, however, never become a general one, and there are abundant reasons why this should be the case. To ascertain accurately the quantity of water consumed per horse power developed by any given engine is practically no very easy matter. In the first place the power exerted by the engine during the trial must be constant—or so nearly constant that the mean power exerted may be accurately estimated—and this is a condition which, except in the case of engines employed for pumping water and a few other instances, is very difficult of attainment for any lengthened period of time. Next, the quantity of water supplied to the boilers must be accurately ascertained, not by water-meters, which are rarely thoroughly accurate, but if possible by direct measurement in a tank or equivalent contrivance, allowance being made for variations of temperature; thirdly, care must be taken that no steam is taken from the the boiler for other purposes than supplying the engine, and that there is no leakage from valves, cocks, etc.; and fourthly, the water level in the boilers should be the same at the termination of the experiment as at its commencement. In the case of marine engines also with boilers worked with salt water, of which a certain proportion has to be blown off at intervals, the amount thus blown off would have to be ascertained. Altogether such experiments require not only careful, but skilled superintendence; and as, to be of practical use, they must be of lengthened duration in order that inaccuracies due to variation of water level, etc., may be as much as possible eliminated, they are necessarily expensive to carry out, and are consequently seldom resorted to.

Having stated the errors and inconveniences incidental to the ordinary methods of comparing the performances of steam engines, it is only fair that we should point out a method of making such comparisons to which the above mentioned objections do not apply. This method is a very simple one, and consists merely in measuring the heat carried off from the engine by the exhaust steam, this steam, this heat being, in the case of a condensing engine, of course imparted to the water used for effecting condensation. It has long been a practice with many engine-drivers to roughly estimate the temperature of the water in the hot wells of their engines, by dipping their hands in it, and in this way to get some rude idea of the manner in which their engines are working; and several engineers, and amongst them Mr. David Thomson, have by supplying an engine with a constant amount of condensing water, and noticing the variations in the temperature of the latter estimated the relative economy of different rates of expansion etc, when working against a given load. The merit, however, of reducing this method of testing engines to a system, and devising means for carrying it out in a simple yet thoroughly accurate manner is due to Mr. B. W. Farey and Mr. Bryan Donkin, jun., of the firm of Messrs. Bryan Donkin and Co., of Bermondsey, who have during the past eighteen months or so ascertained the performances of a number of engines in this way both in this country and abroad. In a letter addressed to us, and which was published in Engineering of the 17th of July last, (*vide* page 58 of our last volume), Mr. Farey drew attention to this mode of testing engines, and gave a description of the apparatus employed; but it may nevertheless be convenient that we should give some particulars of the system here.

The principles upon which the system is founded may be very simply stated. A steam engine is but a form of heat engine, receiving its supply of heat from the boiler, and converting a greater or lesser portion of this heat into useful work. The more efficient the engine the greater will be the proportionate amount of heat thus transformed into work, and the less consequently will be the proportionate quantity carried off by the exhaust steam. We thus see that we measure the quantity of heat carried off by the waste steam of any engine during, say, a minute, and divide this quantity by the number of horse power developed by the engine during that minute, we get a certain number or constant which will enable the performance of that engine to be compared accurately with that of any other engine tested in a similar way. The more efficient the engine the lower, of course, its "constant" will be, and *vice versâ*.

We must next consider the means by which the quantity of heat carried off by the exhaust steam can be measured, and we may here remark that nothing could be more simple, and at the same time more accurate, than the apparatus which Messrs. Farey and B. Donkin, junior, have devised and employed for this purpose. In its simplest and most generally useful form, it consists merely of a wooden trough, or box, into which the whole of the water from the hot-well is led, this trough having several partitions across it, over and under which the water flows, so as to obtain at last a steady current, which, at one end of the trough, falls over a weir or a "tumbling bay." The height or head of water above the weir can be readily determined by the ordinary hook gauge, and this and the breadth of the weir being known, the quantity of water discharged in a given time can be readily and accurately calculated by the use of Beardmore's Tables, or equivalent formulæ. In practice it would be unnecessary to make these calculations more than once for any given apparatus, it being, of course, more convenient to mark on the gauge the discharge per minute corresponding to each given amount of head. To ascertain the temperature at which the condensing water enters the condenser and finally escapes, a good thermometer is, of course, all that is required. The number of degrees that the water is raised in temperature during its passage through the condenser, and the number of pounds of water thus heated during a given time, being known, we can, by merely multiplying these two quantities together, determine the number of pound-degrees of heat or thermal units carried off from the engine during that time by the exhaust steam. Dividing this number of pound-degrees by the number of horse power developed by the engine during the trial, we get the "constant" already mentioned.

All, then, that is necessary to test an engine on Messrs. Farey and Donkin's system is a wooden box with a tumbling bay, a good thermometer, and indicators for determining the power developed. It is by no means necessary that the trial should be a lengthened one, for it will be found that as long as a constant pressure of steam is maintained, and the engine is employed to do an uniform amount of work, the amount of heat carried off by the condensing water will also remain constant from hour to hour, and there is, therefore, no reason why the experiment should be extended for an inconvenient time. This is a very important point in favor of the system of testing of which we are speaking, as in all mills or factories an engine can be kept doing tolerably uniform work for a couple of hours or so without inconvenience, whereas if the trial had to be extended over a lengthened period (as would be essential if the quantity of water evaporated by the boilers and the amount of coal consumed were obtained in the ordinary way) much inconvenience and expense would be in most cases incurred.

We must now speak of another important point connected with this system of testing engines. Mr. Farey and Mr. B. Donkin, junior, have found, from experiments, that the "constant" of any given engine does not vary to any practical extent with moderate variations of power; and thus when the "constant" has once been obtained, the power developed at any given time by an engine fitted with the apparatus we have described can be ascertained very closely without the use of the indicator. For instance, let us suppose that it has been ascertained that the "constant" of any given engine is 480 or, in other words, that the exhaust steam of that engine carries off 480 pound-degrees of heat per minute for every indicated horse power. Then if, on observing the apparatus, it was found that 14,400 units of heat were passing away per minute, the engine would then be developing $\frac{14400}{480} = 30$ horse power, or if 16,800 units were being given off per minute, $\frac{16800}{480} = 35$ horse power would be developed, and so on. We thus see that the apparatus affords a very ready means of estimating the power requisite to drive various machines, shafting, etc., and we are inclined to believe that if it was generally applied to these purposes some curious revelations would be the result.

In cases where it is desired to maintain a continuous registration of the work done by an engine, Messrs. Farey and Donkin employ the simple arrangement of photographic apparatus described and illustrated in the letter from Mr. Farey to which we have already referred. According to this plan, two rays of light from a gas burner—the one passing through a hole in a screen carried by a float, and the other through a break in the mercurial column of a thermometer—are, after traversing lenses, made to fall upon a sheet of sensitized paper carried by a slowly revolving drum, which derives its motion from the engine. Each ray of course traces a line upon the sensitized paper, and by the distance of these lines above or below a fixed datum line traced by a third ray of light, the quantity and temperature of the water passing over the weir at any given time are registered. Applied in this way, the apparatus is calculated to do good service to large millowners and waterworks companies who desire to obtain a continuous record of the performances of their engines.

Hitherto we have spoken of this system of testing as applied to stationary condensing engines only; but it is also applicable to high-pressure engines, and, under certain circumstances, to marine engines. In the case of high-pressure engines, the exhaust steam would have to be turned into a tank of water and condensed, and the water thus heated could then be treated like that from the hot well of a condensing engine. In the case of marine engines, the vessel containing the engines to be tested would have to be lashed alongside a wharf, and the engines being got up to their intended working speed, the water from the hot well would have to be conducted into a box fixed to the wharf, and measured in the way already described. Of course in actual trials at sea some other method of measuring the water discharged from the hot well would have to be devised; but this being done, the system of testing would be as applicable at sea as on shore, as the rise of temperature of the condensing water could of course be readily ascertained.

We have spoken, at some length, of the system of comparing the performances of steam engines proposed by Mr. B. W. Farey and Mr. B. Donkin, jun., because we are convinced that it is one deserving the most attentive consideration of all employers of steam power. The experiments required for its application to any engine are of the most simple and inexpensive kind, and, when once understood, they may be carried out as easily as the taking of an ordinary indicator diagram. The system, moreover, gives for each engine a "constant," the favorableness or unfavorableness of which is entirely dependent on the performance of the engine itself, and which is not affected in any way by the efficiency or inefficiency of the boilers, by the quality of the coal used, or by the greater or less skill of the stoker. Once let such a standard of comparison as this become generally adopted, and we shall hear less of vague performances and more of really economical steam engine—a state of affairs earnestly to be desired.

Loads on Girders.—At a recent meeting of the Société des Ingénieurs Civils M. Leygue presented to the Société a detailed study on uniformly distributed loads, which, in their results, are equivalent to the loads caused by traffic on metal superstructures; that is to say, capable of producing in the sections submitted to the greatest strains caused by separate loads, the same maxima momenta of flexion.

M. Leygue first examined the conditions of variation, to the extent of the movement of the loads, of the maxima momenta produced by a series of forces, P, acting on a body resting freely on two level supports. In discussing the expression

$$\mu = A + B\,z,$$

which is the usual formula of flexion momenta for any section, he found that in the position, z, the most unfavorable of the system, one of the loads, P, was to be found in the section undergoing the greatest strain.

From this point the question of uniformly distributed loads becomes remarkably simplified.

If x be the abscissa of the maximum momentum under any specified load; π the uniformly distributed load producing the same effect as the separate loads, P; L the bearing of the girder; p the uniformly distributed load caused by the dead weight; F the resultant of distinct forces, P′; λ the distance of the load under consideration to the resultant, F; Σ P l the sum of the momenta in relation to the load under consideration, of the separate loads placed at certain distances on the abscissa x, we find

$$x = \frac{L}{2} - \lambda \frac{F}{2F + pL}$$

and

$$\pi = \frac{2F}{L}\left(1 - \frac{\lambda}{L - x}\right) - \frac{2\Sigma Pl}{(L - x)x}.$$

After having examined the conclusions to be deducted from these formulæ, M. Leygue presented to the Société the results of their application to underline and overline roadways. The calculations are arranged in the shape of tables and curves, in which the values π are considered as representing the performance of the bearings of the girders.

The general shape of the curves thus traced is hyperbolical with two rectangular asymptotes:

$$x = o \text{ and } y = \text{constant}.$$

In face of such results, and foreseeing what must take place in other companies from what has taken place in the Compagnie du Nord, M. Leygue was surprised that straight lines of 400 K., 4,000 K., and 5,000 K., should still be the standard indications in the administrative orders of the controller's office. It would seem to be more reasonable to permit the engineers to fix upon the loads for which they must calculate their works, and to simply place a certain limit to the molecular strains to which the metals may be submitted. In fact, the different pitches would allow the degree of stability of the works to be ascertained.

M. Leygue believed that the figures obtained by the formula (π) were also applicable to continuous girders supported by several bays. In fact, in a case of entire symmetry there will be found for a piece built in horizontally at both its extremities,

$$\pi = \frac{N(N+2)}{N+1} \cdot \frac{P}{L},$$

N representing the number of separate loads, P, distributed on the bay L; and this formula will be found *identical* in the hypothesis of free supports.

M. Leygue concluded by saying that he agreed with the expressed opinion of M. Bresse that the motion of the loads ought not to have a disturbing influence on the works. If certain observations seem to contradict this opinion, the reason probably is that the girders, by the relation of their component parts, were placed beyond the typical limits as regards which theory and practice are not in contradiction to each other. For this reason M. Leygue supported without any alteration the figures obtained by him, deduction being made for the speed of the rolling loads.

THE IRON AND STEEL INSTITUTE OF GREAT BRITAIN.—This body comprises upwards of 140 of the leading iron and steel masters, managers and engineers of the kingdom. Its objects as defined in the printed rules are, 1st, to afford the means of communication between members of the iron and steel trades upon matters bearing upon the respective manufactures, excluding all questions connected with wages and trade regulations; 2d, to arrange periodical meetings for the purpose of discussing practical and scientific subjects bearing upon the manufacture and working of iron and steel. The several similar institutions devoted more especially to civil engineering have proved of such signal advantage to all concerned, that great hopes are entertained of the usefulness of this new enterprise.

GOLD REGION IN SOUTH AFRICA.—"Peterman's Mittheilungen" contains a report on the gold region discovered by K. Mausch, in the south of Africa, between Limpopo and Zambesi. Quartz rock, very rich in gold, is found there extending over a length of many miles. Gold sand rich enough to be washed to advantage has not yet been discovered. Captain Black, who has acquired a considerable experience in gold mining in California, is managing the mining operations. He wishes to annex this gold district to the Cape Colony, and has given it the name of Victoria district. Gold mining companies have been organized in Natal, in the Transvaal Republic, and in the Cape Colony. Several European geologists have started for Africa. A scientific man is being sent there from England. Already, in October last, Germany sent Mr. Ed. Mohr, the experienced traveller, well acquainted with the south of Africa, and accompanied by O. Hübener, of the Freiberg Mining Academy. They have gone to Natal and the Transvaal Republic with the purpose of subjecting the gold district mentioned to a closer investigation.—*Oestr. Zeitschrift.*

New Method of Rifling and Working Heavy Guns.—The "Mechanics' Magazine" for May 14, 1869, illustrates in detail the scheme referred to, as designed by Mr. C. Pemberton, of the Royal Navy. A rifled bar of say 6 in. diameter is screwed into the bottom of the chamber and occupies the position in the bore that a piston-rod would occupy in a cylinder. The projectile is bored out and grooved to fit over this rifled bar, while the exterior of the projectile and the bore of the gun are smooth. The object is to avoid the weakening of the gun by the loss of metal and the sharp angles of grooves in the bore, and by the bursting strain caused by the rotation of the projectile. It appears to us, however, that the rifled bar would sag at the muzzle to such an extent as to make loading difficult.

Mr. Pemberton also shows a novel arrangement of air cylinder for taking up the recoil, and also for running out the gun; also a method of elevating the gun platform by screws, which we think vastly inferior to hydraulic power.

BLAST FURNACE ECONOMY.

From "Engineering."

To those who desire to effect economy in the carrying out of any process or manufacturing operation there is no knowledge more valuable than a knowledge of all existing sources of waste. In some cases such knowledge is easy to obtain; but in the majority of instances it is more or less difficult, and in none more so than in those in which the matter to be economized is fuel. Let us take the steam engine for example. We know that a certain quantity of fuel if properly consumed will produce a certain number of units of heat, and that if this number is multiplied by 772 we get the number of foot-pounds of work which this heat is capable of developing if completely utilised. But we also know that even with the best boilers and engines now constructed the amount of work actually developed falls immensely short of this theoretical quantity; there are losses caused by imperfect combustion, by heat carried off from the boiler furnaces, by the waste gases, by radiation, by condensation, by wire-drawing, by leakage, and by numbers of other defects, which it is unnecessary to mention here. The losses due to some of these various causes are known with tolerable accuracy, but with regard to others there is little definite information available, and the consequence is that they are not guarded against as they should be. If we knew exactly how every unit of heat developed in a boiler furnace is expended, who can doubt but that some substantial improvement in construction would be the result.

As with steam engines so with blast furnaces, respecting which we intend more especially to speak on the present occasion. That much has been done during the past few years—and particularly in the Cleveland district—to reduce the consumption of fuel in blast furnaces per ton of iron produced is undeniable; but it is equally undeniable that there is still margin for improvement, and it appears to us that one of the first steps to be made towards effecting that improvement is to ascertain with the greatest practicable exactness the losses amounting from each existing source of waste. These losses once known, they may be considered separately, and means taken to avoid them.

At the meeting of the Institution of Mechanical Engineers, held on the 28th of January last, during the discussion which took place on Mr. Cochrane's paper on the utilisation of waste gases from blast furnaces,* attention was especially directed to the differences which exist between the quantities of fuel actually consumed in blast furnaces per ton of iron produced, and the amounts which would be theoretically required; and the subject is altogether one of such importance as to deserve especial consideration. And here we may remark that it is quite impossible in the present state of our metallurgical knowledge to say precisely how much fuel is absolutely wasted in any given blast furnace. The quantities of fuel, ore, and fluxes introduced in any given time, and their analyses, may be accurately known to us; but our information concerning the quantities of heat rendered latent in destroying certain chemical combinations, the heat absorbed is liquefying the slag and iron itself; the specific heat of the liquid slag and iron, and other matters, is far from being so reliable as we could wish, and, consequently, as we have said, a thoroughly accurate estimate of the fuel required in any

* See Van Nostrand's Magazine, No. 2, p. 140.

given instance cannot, at present, be given. Notwithstanding this, however, we have sufficient data at our disposal to show that the amount of fuel actually used is greater than it should be, and it may be interesting if we consider this matter more closely. For this purpose it will be convenient if we take, as an example, a furnace worked with certain definite charges of ore and fuel, and show how the proportions between those charges agree with those which would be theoretically required.

Let us, for instance, consider a furnace, in which the charges consist of 26 cwt. of coke, 50 cwt. of ironstone, and 10 cwt. of limestone, per ton of iron run; the ironstone containing 40 per cent. of iron in the state of peroxide. We have chosen these proportions because they will enable us to readily compare our calculations with those of Mr. I. Lowthian Bell and Mr. Siemens given in the course of the discussion to which we have already referred; and which were founded on similar data. In the first place the coke used in the Cleveland district contains from 5 to 10 per cent. of ash and moisture, and if we assume that our particular sample contains $7\frac{1}{2}$ per cent. of these matters, we shall have to make a deduction of $1\frac{1}{2}$ cwt. from the quantity available as fuel. A further deduction of about 1 cwt. will have to be made for the carbon which combines with the iron, leaving finally $23\frac{1}{2}$ cwt. of carbon to be accounted for.

Peroxide of iron (Fe_2O_3) consists of 56 parts by weight of iron combined with 24 of oxygen, and the 50 cwt. of ironstone charged per ton of iron made contain, therefore, 20 cwt. of iron, 8.57 cwt. of oxygen, and 21.43 cwt. of other materials, principally silica. The decomposition of the peroxide is effected by its oxygen being taken up by the carbonic oxide gas produced by the imperfect combustion of the coke, this carbonic oxide being thus converted into carbonic acid. The amount of carbonic oxide required to decompose the given quantity of peroxide of iron is readily calculated. Carbonic oxide consisting of 6 parts by weight of carbon combined with 8 parts of oxygen, and carbonic acid consisting of 6 parts of carbon and 16 of oxygen, it follows that to take up the 8.57 cwt. of oxygen from the peroxide of iron 15 cwt. of carbonic oxide (composed of 6.43 cwts. of carbon and 8.57 cwt. of oxygen) will be necessary. This disposes of 6.43 cwt. out of the $23\frac{1}{2}$ cwt. of carbon. But in converting the oxygen of the peroxide from the solid to the gaseous form there is a great absorption of heat, and to supply this heat a consumption of fuel has to take place. It appears from the researches of Ebelmen and Schinz that the quantity of heat rendered latent during the decomposition of the peroxide of iron amounts to 718 units for each pound of oxide decomposed, and as in our example the quantity of peroxide is 28.57 cwt., the heat absorbed would be $28.57 \times 112 \times 718 = 229{,}748{,}512$ units. We must next consider the quantity of fuel required to supply this amount of heat.

If the whole of the carbon consumed in a blast furnace was converted into carbonic acid, each pound of it would develop about 14,000 units of heat; but, as a fact, it appears probable that, as estimated by Mr. Siemens, not more than one-fifth is thus converted, the remaining four-fifths assuming the form of carbonic oxide. As carbon, when burnt into carbonic oxide, only produces about 4,000 units of heat, we thus have as the average quantity of heat produced by each pound of carbon consumed in the furnace $(\frac{1}{5} \times 14{,}000) + (\frac{4}{5} \times 4{,}000) = 6{,}000$ units; and this we believe is a fair estimate. From these data we get $\frac{229{,}748{,}512}{6{,}000 \times 112} = 3.418$, or, say, 3.42 cwt. as the quantity of fuel required to supply the heat rendered latent during the decomposition of the peroxide of iron. We have next to consider the amount of heat rendered latent during the decomposition of the limestone; and, according to the experiments of Schinz, this amounts to 355 units for each pound of carbonate of lime decomposed. In our case, therefore, the quantity will be $10 \times 112 \times 355 = 397{,}600$ units corresponding to the consumption of $\frac{397{,}600}{6{,}000 \times 112} = 0.591$, or, say, 0.6 cwt. of fuel.

At the time that the iron and slag are discharged from a blast furnace they have a temperature which may be fairly assumed as about 2,400° higher than that of the materials at the time of charging; and we have now to consider the amount of heat necessary to liquefy them and give them this high temperature. The amount of heat rendered latent during the liquefaction of a pound of cast iron has been given by Clement as 233 units, and by Schinz as varying in different samples from 250 to 315 units. If we assume 250 units as the amount in the present case, we shall have $250 \times 20 \times 112 = 560{,}000$ units as the amount rendered latent during the liquefaction of the ton of iron. Again, the specific heat of cast iron in the solid state is 0.13, and in the liquid state about 0.16; and we shall, therefore, have $20 \times 112 \times 0.13 \times 2{,}000 = 582{,}400$ units of heat absorbed in raising the ton of iron to the melting point, and $20 \times 112 \times 0.16 \times 400 = 143{,}360$ units imparted to it after it is melted. Adding these quantities together, we get $560{,}000 + 582{,}400 + 143{,}360 = 1{,}285{,}760$ units; thus corresponding to the consumption of $\frac{1{,}285{,}760}{6{,}000 \times 112} = 1.91$ cwt. of fuel.

As to the quantity of heat rendered latent during the liquefaction of the slag, some little uncertainty exists, and it, moreover, no doubt varies in slags of different compositions. The researches of various continental experimenters, however, tend to show that 110 units per pound of slag melted may be taken as a fair estimate in ordinary cases. With the charges mentioned in our example, the quantity of slag produced would be about $29\frac{1}{2}$ or 30 cwt. per ton of iron made, and taking the latter quantity, we shall have $30 \times 112 \times 110 = 369{,}600$ units. The specific heat of slag, like that of iron, varies according to whether the material is in the solid or liquid form; but we may, without any serious error, assume it as being 0.2 throughout. The quantity of heat required to raise the temperature of the materials forming the slag about 2,400°, will thus be $2{,}400 \times 30 \times 112 \times 0.2 = 1{,}612{,}800$ units; and adding to this the 369,600 units absorbed during liquefaction, we get 1,982,400 units as to the total heat imparted to the slag, this corresponding to the consumption of $\frac{1{,}982{,}400}{6{,}000 \times 112} = 2.94$, or, say, 3 cwt. of fuel.

Summarizing the results above obtained, we get the following statement of the manner in which the 26 cwt. of fuel is disposed of:

	cwt.
Ashes and moisture in fuel	1.5
Carbonization of the melted iron	1.0
Carbon for combining with oxygen in ore	6.43
Fuel for melting iron	1.91
" " slag	3.0
" to supply heat rendered latent during decomposition of ironstone	3.42
" ditto during decomposition of linestone,	0.6
	17.86
Not accounted for above	8.14
Total	26.0

In the above summary we have taken no account of the heat carried off by the waste gases escaping at the mouth of the furnace, for we quite agree with Mr. Siemens in considering that this amount is more than balanced by the heat introduced into the furnace by the hot blast, supposing the latter to be heated to, say, 1,000°. A simple calculation will prove this. We have shown that of the 26 cwt. of coke, $23\frac{1}{2}$ cwt. would be actually consumed as fuel (for the amount which unites with the oxygen of the ore is really consumed), and of this quantity we have assumed one-fifth or 4.7 cwt. to be converted into carbonic acid, and the remainder, or 18.8 cwt., into carbonic oxide. The 4.7 cwt. converted into carbonic acid, would require $\frac{4.7 \times 16}{6} = 12.63$ cwt. of oxygen for their conversion, whilst the remaining 18.8 cwt. would combine with $\frac{18.8 \times 8}{6} = 25.06$ cwt. of oxygen in forming carbonic oxide. The total quantity of oxygen required for chemical combination alone would thus be $12.63 + 25.06 = 37.69$ cwt., and of this quantity 8.57 cwt. would be supplied by the iron ore, leaving 29.12, or, say, 29 cwt. to be provided by the blast. Taking the air as being composed of 22 per cent., by weight, of oxygen, 77 per cent. of nitrogen, and 1 per cent. of moisture, carbonic acid, &c., we have $\frac{29 \times 100}{22} = 131.7$, or, say, 132 cwt. of blast as the amount necessary to furnish the above supply of oxygen. The specific heat of air being 0.238, this quantity of blast if heated 1,000°, above the ordinary atmospheric temperature, will thus introduce into the furnace $1{,}000 \times 0.238 \times 132 \times 112 = 3{,}518{,}592$ units of heat.

On the other hand, the gases escaping from the mouth of the furnace consist of 4.4 cwt. of carbonic acid derived from the limestone, 8.57 cwt. of oxygen from the peroxide of iron, 132 cwt. of oxygen, nitrogen, &c., from the blast, and 23.5 cwt. of carbon, combined with the oxygen of the air and that from the peroxide of iron, in the form of carbonic acid and carbonic oxide. The total weight of the gases will thus be $4.4 + 8.57 + 132 + 22.5 = 168.47$, or, say, $168\frac{1}{2}$ cwt. Taking the specific heat of these mixed gases to be 0.24, and their temperature to be 600°, we shall thus have $169.5 \times 112 \times 0.24 \times 600 = 2{,}717{,}568$ units of heat carried off by them, this quantity being $3{,}518{,}592 - 2{,}717{,}568 = 801{,}024$ units less than is introduced by the blast. To some extent this over-plus would no doubt be reduced by the heat carried off by radiation from the pipes by the water circulating through the tuyeres, &c., but we think there can be little doubt that the heat introduced by the hot blast will fully compensate for that carried off by the waste gases.

It may be interesting if we compare our calculations as to the disposal of the fuel above given with the estimates given by Mr. I. Lowthian Bell and Mr. Siemens on the occasion of the discussion to which we have already referred. Mr. Bell's estimate was as follows:

	cwt.
Carbonization of the melted iron	1.0
Melting the iron, and keeping it melted on the hearth...........................	2.7
Ditto as regards the cinder	4.5
Heat carried off by the escaping gases	6.36
Heat rendered latent, including the 6.43 cwt. of carbon combining with the oxygen in the ore, say, altogether	9.00
Total	23.56

It will be noticed that in the above estimate, although Mr. Bell allows 6.36 cwt. as the equivalent of fuel carried off by the waste gases, he makes no allowance for the heat introduced by the blast. Assuming, as we have done, that these two quantities balance each other, and deducting from Mr. Bell's estimate the 6.36 cwt. just mentioned, we get, as a remainder, 17.2 cwt., a quantity closely agreeing with that shown by our own calculations. Mr. Siemens' estimate, which also agrees closely with our own, was as follows:

	cwt.	
Melting the iron....................	1.60	
Melting the cinder..................	4.13	
Heat rendered latent by reduction of ore,	3.19	
Carbon for combining with oxygen in ore and for carbonizing pig metal...	7.43	
		16.35
Ashes and water in coke, 10 per cent......		1.63
Calcining the limestone, &c., 10 per cent...		1.63
Total quantity of coke required.........		19.61

Of the 8.14 cwt. of coke per ton of iron, given in our own estimate as unaccounted for by the useful work done, a portion is no doubt expended in supplying the heat lost by radiation from the furnace, but we have no reliable data which will enable us to estimate what the amount of this loss will be. There is, however, little cause for supposing that it is sufficient to account for the heat generated by the combustion of about one-third of the total quantity of fuel, and there must therefore be some other sources of waste not sufficiently recognized, but which it is desirable should be sought after and, if possible, avoided. The demand upon our space will not permit us to say more on this subject here; but we intend to return to it on an early occasion.

THE MARTIN STEEL PROCESS.

Condensed and translated from a paper published by CONSTANTIN PEIPERS, Messrs. Martin's representative in Prussia.

Among the great number of new processes of steel manufacture invented within the last decade, the Martin process has been practically the most successful, and may perhaps in its further development stand side by side in importance with the Bessemer process. Though not attracting attention by any new or peculiarly original idea, it has rapidly come into extensive use by the great practical value it has for certain branches of the iron and steel manufacture.

It was on the 4th of April, 1864, when Mr. Martin, in his establishment at Sireuil, near Angoulême, first succeeded in making cast steel on the hearth of a regenerative furnace. The process was patented in France on the 10th of August in the same year. To-day, five years after this first successful trial, the process is worked in many places in France, and has been introduced into almost all the other industrial countries. The larger establishments accept and fill considerable orders for rails and tyres of Martin steel. Martin, himself, has manufactured gun-barrels regularly and without interruption since 1865. The furnace he uses for this purpose is producing one and a half millions of pounds of steel per year. Thus the process may be considered as a decided practical success. Also the technical journals and the highest metallurgical authorities have expressed their belief in the great future of this process.

The idea on which the Martin process is based is not new. Heath took a patent on it as early as 1839.* Numerous experiments have been made by others in the same direction, but without decisive success. Though Martin is not, therefore, the original inventor of the process called by his name, he has the great and undoubted merit of having found out, by numerous and costly experiments, the right proportions in the construction of the furnace and gas-producer, the most suit-

* Heath's patent of 1845 (see Van Nostrand's Mag., No. 6, p. 547) more nearly describes it.—ED.

able materials for the process, and the best manner of manipulating the same. Martin has given to the industrial world not a mere idea, but a complete method of manufacture, developed in its details, and perfected at a considerable experience.*

The general principle in this process is well known, and can be mentioned here in but a few words. A certain quantity of pig iron is melted on the concave hearth of a reverberatory furnace, together with some slag to cover the iron and to protect it from the direct influence of the air and the gases. Small portions of wrought iron are thrown successively into this iron bath, which operation is continued until a test taken from the furnace shows that the whole mass of iron possesses the softness and other properties of wrought iron. This melted soft iron is finally reconverted into steel by the addition of a well proportioned quantity of pig iron. The heat necessary for these operations is partly furnished by a regenerator connected with the reverberatory furnace. The wrought iron to be added may consist of hot puddle-balls just obtained from a neighboring puddling furnace; or wrought iron scraps may be used, being previously heated in a separate furnace, or by the waste heat of a heating furnace. The product of the process is tapped and run into molds, or cast into any required shape.

We intend to show, by the following remarks, what relative position the Martin process will occupy to the other modes of making cast steel now in use; how its results and products compare with those of the crucible and the Bessemer process; and how the new process, in remedying some of the disadvantages of both the above, fills a gap between them, and can be made useful to both.

It is hardly necessary to mention that the Martin process is a much cheaper method of making cast steel than the usual crucible process. It compares in cheapness, under favorable circumstances, even with the Bessemer process, with which it has in a few instances come into actual competition. Though mostly used as yet for the production of larger masses of steel, the Martin process is capable of producing also the finer and harder kinds of steel for tools and cutting instruments, though not of a very superior quality.

The best crucible steel is made in Westphalia, and partly also in Austria, by melting wrought iron together with cast iron. The same thing is done in the Martin furnace, which is in fact a large crucible, the metal being protected by a layer of melted slag. As, however, this process, when carried out in the crucible, requires but nine per cent of pig iron, the Martin process on the other hand using from 30 to 50 per cent, the products of the latter are liable to be somewhat less pure and of a lower quality than those of the crucible process, when worked with similar raw materials. But this can be remedied to a considerable extent by the use of chemicals, which Mr. Martin has used for this purpose with eminent success. Thus the Martin process will enable the cast steel manufacturers to produce their ordinary kinds of steel, which are the most in demand, at a very much lower cost than before. Another circumstance that will lead them to introduce the Martin process is this, that it offers a greater security for producing exactly the required degree of hardness than the crucible process. The latter uses a good many materials, the composition or qualities of which cannot always be exactly known, and it does not present any facility for testing the product before it is poured. In the Martin process, on the contrary, samples can be taken at any time from the steel or iron bath, and the composition of the baths can be easily altered, until it has obtained the desired qualities. The softest kinds of steel which it is so difficult to produce in crucibles, can be made in the Martin furnace with the same degree of security as the harder kinds, avoiding at the same time all the losses and irregularities often caused by the cracking and breaking of crucibles. It is therefore to be expected that the cast steel manufacturers will, for the greater part of their production, replace the crucible melting by the Martin process.

When compared to the pneumatic process, Martin's method may be said to furnish products equal in quality to the best, and superior to the ordinary makes of Bessemer steel, supposing similar raw materials to be used. This is owing, in the first place, to the above mentioned facility of controling the operations in a Martin furnace. The samples taken from time to time show the condition of the metal at any moment, and indicate exactly the point when the metal resembles wrought iron in its qualities, and when it has to be recarburized by a certain

* If Martin added enough to a process that had been abandoned to make it practicable, the patent for his invention is of course valid.—Ed.

weight of pig iron. After being recarburized the metal is kept in the furnace three-quarters of an hour to effect an even distribution of the carbon, thus insuring a perfectly uniform product. During this time the metal has ample time to complete the boil, to discharge all the gases generated in its interior by the previous reactions, and to settle down, forming a quiet homogeneous bath. After this it pours without bubbling, and produces ingots free from cavities or flaws. A sample taken a short time before pouring gives a perfect assurance in regard to its qualities. The tapping of the metal can be done in a larger or smaller stream, as required, thus allowing of its being poured into large molds or used for small castings, for which it is well adapted.

The fitness of a pig iron for the steel manufacture depends principally on the percentage of phosphorus it contains. As puddling purifies pig iron from phosphorus to a considerable extent in converting it into wrought iron, the Martin process, in using this purified wrought iron must also, from this reason, produce a better quality of steel from the same pig iron than the pneumatic process, by which a purification of this kind is not effected. This makes it possible that the Martin process may be worked with success in districts which produce a pig iron not sufficiently pure to make a good Bessemer steel, and from which the Bessemer process is consequently excluded. The plant required by the latter is, besides, much more expensive.

These considerations may be apt to induce Bessemer works, in whose interest it is to monopolize the production of the larger steel castings, to erect Martin furnaces for the purpose of making such castings of a better quality and more perfect soundness. But the Martin process is, besides, in another respect, of great value to Bessemer works, by its being eminently adapted to use up all their scraps, spillings and cuttings in the most advantageous manner that can be imagined.

The greater the progress and the extension of the manufacture of Bessemer rails and Bessemer tyres, the greater importance will the Martin process acquire, because it is adapted and necessary to work the old materials up again.

The Martin process cannot directly make a good steel from inferior pig iron. The pig iron it uses as such must be pure. But it can use to about equal advantage gray iron, spiegeleisen or white iron. Spiegeleisen, which plays such an important part in all the branches of steel manufacture, is also in the Martin process of a very high value. The results obtained with it, when used for the first bath in the Martin charge, were astonishing, the products combining a great natural hardness and solidity, with a high degree of toughness.

A Martin furnace can be worked together with puddling furnaces to great advantage, in which case a separate heating furnace can be dispensed with. The iron in the puddling furnace can, immediately after the boil, be taken into the Martin bath. This way of operating presents an excellent opportunity for the use of chemicals to purify and improve the products. For the pasty condition of the puddled iron, before being balled, makes it well adapted to be mixed with all kinds of chemical re-agents, which afterwards come in very intimate contact with the steel bath when the iron is thrown into it. Martin has made extensive experiments in this direction with remarkable success, especially in working inferior brands of pig iron. This process offers, in general, greater facilities for the use of chemicals than any other method of making steel, and is therefore highly capable of being improved and perfected by new inventions, which quality still more insures its future importance.

S.

RAILWAY DISASTERS—THE CAUSE.

Taking the verdict of the Coroner's jury in the late Long Island Railroad disaster as a text—a broken rail—"The Engineer" observes that such casualties in America are usually attributed to bad Welch rails, admits that much very bad iron has been sent us thence, and concludes, first, that it is "criminal" for American managers to buy iron that they know to be unsafe, and, 2d, that American rails are "ill used." This authority further says:

The exceptionally evil influences to which track is subjected in America may be classed under two heads; defects in the method of laying, and defects in the rolling stock. And here we may add that bad rolling stock causes quite as many accidents in the States as bad track.

As regards defects in the method of laying, it will suffice to state that, with exception of a few first-class lines on which accidents rarely occur, ballasting is nearly unknown. The consequence is a continually recurring irregular subsidence of the line, which renders it impossible that the rails can be equally supported at intervals throughout their length. In many cases, it is certain that double the proper distance practically intervenes between chair and chair, or sleeper and sleeper.* We need not stop to point out how severe a strain this throws on the rails. Furthermore, fishing is almost unknown, and rails are laid so badly, and keyed into the chairs after so slovenly a fashion † that they are exposed to a great deal of unnecessary pounding and hammering, sufficient under the circumstances to deteriorate any rails. If the substructure of American roads were better we should have fewer complaints regarding the bad quality of superstructure, that is, of the rails.

We have said that defective rolling-stock contributes to the destruction of rails in America, and we may repeat that it is quite as fruitful a source of disaster as the bad quality of rails. We constantly read in the American papers of fearful catastrophes due to the bursting of track. In the great majority of cases rails in the States are broken laterally, not vertically. Now it is claimed for the American bogie car that it, beyond all other machines, runs lightly. How is it, then, that track is so often burst? How is it that derailment is so common an occurrence in the States? We are always told that the fault is in the track, yet it has been proved over and over again that the track was good and sound, and that no ordinary violence must have been exerted to break it. All this while, too, no one has questioned the merits of the American car, with its bogie at each end; yet in this system of constructing rolling-stock there is reason to believe that the seat of much of the mischief lies. The Willow Tree accident supplies us with a case in point. After carefully perusing the evidence, we are led to the conclusion that the verdict we have recorded above is wrong; and one juror, Mr. Pearsall, after the rendition of the verdict, read the following statement as his positive belief in the matter:

"As one of the jurors sworn to inquire into all the facts and circumstances attending the deaths of William C. Rushmore, &c., I do find that the said persons came to their deaths from an accident to the car in which they were passengers, the car being thrown from the track, and from all the testimony in the case I am unable to arrive at the cause of the accident."

And he and other jurors added that they could not find anything peculiarly defective in the road, or likely to lead to the accident. There appears, indeed, to be no doubt whatever that the car which left the track got off first, ran for more than a hundred yards on the sleepers, and then broke a rail. Under such circumstances, it is obviously wrong to say that the bad quality of the rail had anything to do with the catastrophe.

The fact is, that bogies, as often fitted to American railway carriages—we beg pardon, "cars"—are very liable to get off the track. It is not unusual to make the wheel base of each bogie shorter than the distance between the rails. The consequence is, that the bogie runs with a sinuous movement, alternately jostling right and left. The cast-iron wheels are not always properly matched in diameter, and thus a constant tendency may exist for one side of the bogie to outrun the other. The cars are not coupled up tight in the train as with us, and they therefore cannot steady the wandering bogie. No one part of the train is a check on the rest, and therefore the chances of derailment are greatly multiplied. We need hardly stop to point out how severely the "wobbling" of a pair of short bogies stuck at each end of a tremendously long carriage, itself oscillating, must try the lateral strength of any track. Yankee engineers are disposed to laugh at our four-wheeled carriages, and to call us behind the age. We fancy that they would find it worth while just to try some of our rolling stock for a while. They have something to learn yet at the other side of the Atlantic from English engineers.

In conclusion, we may state that a letter on the Willow Tree accident, written by a Mr. Wood, has recently appeared in the "New York Times," which bears American testimony to the cogency of not a few of our arguments, as will be seen by the following extracts:

"As a resident landed proprietor along the line, permit me to write a few words with regard to it. The true solution of the matter is that the driver was going at unusual speed, and the last car oscillated from the track, striking and rebounding from the sleepers as it was dragged along, until it loosened a rail which jumped up and had its end caught in the truck-work of the car, which, still being urged on, bent and broke the rail in five places!

"*The true remedy for such mishaps is proper coup-*

* This is a very unusual defect in American track. Indeed, sleepers are often laid too close for proper tamping.—Ed.

† That is to say, not keyed into the chairs at all, the chair being, in most cases, a mere resting for the rail ends.—Ed.

lers, such as the English have, or better still, Miller's automatic coupling, used by the Erie and other great companies. Horrible as was the loss of life, it is well it was no worse under the circumstances; *but until more effective means of retaining the cars on the track when running at high speed be adopted, such will periodically occur*, though I believe the risk was and is aggravated on the Long Island Railroad by bad spiking, inferior iron, deficient ties, and a scamping of the work generally."

"The Engineer" is obviously not aware that the spread truck is usually employed, rather than the short truck, the defect of which it correctly points out. The merits of a properly constructed truck, as compared with a wheel-base the entire length of a car, are evident on mechanical principles, and besides this, they have been proved on the Canadian lines where the two systems have been used side by side. But the dangers arising from unmatched wheels, and especially from the want of the close, tight coupling of car to car, are very great, and should be more seriously and widely considered by our railway managers.

IRON FOUNDING.

"CASTING IN OR ON" TO THE SAME OR TO OTHER METALS—CONSTRUCTION OF FRAMES AND RAILINGS.

From "The Practical Mechanic's Journal."

When we say other metals, we practically mean cast iron, wrought iron, or steel, for no other metals occurring on the large scale in the arts have fusing temperatures such as admit of the processes about to be referred to being applied to them. Occasionally, though rarely, a few substances, not metallic, may be perhaps usefully treated, by the methods of "casting in or on"—for example, grit-stone or blocks of emery might be run round with cast iron so as to unite these into large grinding plates or cylindric surfaces and the like; but these are out of our way just now.

Whenever liquid cast iron, of whatever kind, is brought into contact with a comparatively cold surface of good conducting material, it is, as we have already seen, more or less "chilled;" its texture is altered, its hardness increased with its absolute cohesion, but its toughness diminished. This occurs more or less whenever a piece of wrought iron, or of steel, or of cast iron, cold or but moderately heated, is laid into a sand or loam mould, and the liquid iron which fills the mould comes into contact with it. Conversely, the wrought iron or the steel (and even less completely, and with somewhat different conditions), the cast iron with which the liquid cast iron has been brought into contact, and with which it has to cool slowly, and at the same rate, have their molecular status changed also. The wrought iron loses in ultimate cohesion and likewise in toughness, and new crystalline arrangements are formed within its mass, which, on the whole, deteriorate it as a structural material. Changes of like character are produced in steel, but not to the same extent, and tend rather to the enlargement of its constituent crystals than to materially injure it as a structural substance.

Theory alone would thus appear to place its ban upon any such operation as "casting in or on," and in some cases the verdict of mere theory would be approved as true, in its application to practice. Yet there are very many cases occurring in the every-day work of the iron-founder and mechanical engineer, in which the convenience and the economy of this method of uniting the metals are so great, and the changes induced upon both so unimportant, that theory is wisely overlooked or overridden in practice. Before alluding to some of these, let us take a glance at some of the cases in which theory *ought* to be our guide here, and in which the neglect of it is nearly certain to bring the practician to grief. This will be the case whenever it is important that the full and undiminished strength and toughness of both metals, the wrought iron and the cast iron, should be preserved.

The "crucial instance" of a case in which this is indispensable may be said to be found in the construction of artillery, machines in which every particle of the constituent material is simultaneously strained in three directions at right angles to each other, and by force suddenly or impulsively applied, and always so great as to bear a large ratio to the ultimate or crippling strain of the metal. Here, then, of all others, is the case in which "casting in" should have been avoided. Yet the method of making cannon by casting bronze or cast iron round a wrought iron or steel interior tube has been again and again proposed and often tried. In the older days of iron metallurgy, when these subjects were less distinctly understood, and when want of good tools gave some strong inducements, on economic grounds this method was excusable. The very same proposition has been but recently revived, however, by Major Palliser; and it was not before a large gun was blown to pieces at, we believe, the first round, at

Woolwich, that the inventor, with infinite candor, publicly declared that thenceforth he abandoned his method (which was not his, in fact), and conceded his adhesion, when too late, to the indications of theory. We are not always called upon to provide for such strains as cannon are exposed to, but whenever the strains upon any machine or structure are severe, and especially when they are impulsive, we shall do well to avoid "casting in."

Yet cases continually occur in practice where, even upon a very large scale, this method of combining the metals by laying the wrought iron into the mould and casting the cast iron round it, may be practiced with advantage and safety.

Thus, for example, in some of the great iron latticed viaducts upon the Commentry and Gannat branch line of the great Orleans system of railways in France, Mr. Nordling, C. E., the engineer-in-chief, has adopted the suggestion made to him by M. Eiffel, the founder and contractor for the iron-work of La Sioule Viaduct, and has united the corner or gusset plates of wrought iron with the cylindrical columns or shafts of the iron piers (which are of vast altitude), by casting the former into the cast iron of the columns. The success of the process appears to be complete in this instance. Here the mass of cast iron in immediate contact with the wrought iron is relatively large. There is, therefore, no very serious deterioration produced in the cast iron, which is the metal the more obnoxious to injury of the two; and on the other hand, the margin of safety allowed in all parts of these structures, and more particularly in the mass of these gusset plates, admits of some deterioration in the wrought iron constituting them, without running any risk.

To pass to the other extreme in point of dimension, we see this method in continual use amongst the founders of ornamental castings, such as light balusters, balcony panels, &c., into the sand moulds for which are laid short pieces of iron rod or wire, which, when "cast into" the extremities of these castings, become the means by which they are united by screw nutting or by riveting with the hand-rails and other parts of the architectural structures into which they enter. Here, as both cast and wrought iron are small in scantling, and the subsequent strains are small, some loss of strength or toughness can be afforded in consideration of economy.

Our chief aim now is to point out how largely and advantageously this method may have its use extended, and to give some examples. Let us first, however, recur in some degree to theory, and in the way of correcting a very prevalent error amongst many who might be presumed to know better, as to what *can* be effected by this method of casting in. It has been supposed over and over again that additional strength and toughness may be conferred upon castings in iron, by including in their interior a wrought-iron skeleton, which the cast iron, when run around it, shall clothe with itself, as the flesh encloses the bones of an animal. Thus, to quote but one example, several years ago, in the early days of railways, the late Mr. George Forrester, of Vauxhall Foundry, Liverpool, patented a method for making improved cast-iron wheels for railway wagons, by riveting or welding together in a rough and cheap way, a sort of skeleton wrought-iron wheel. This was tinned or galvanized, and after having been warmed, was laid in the dry sand mould, and the cast-iron wheel was poured and formed around it.

Such wheels, proved admittedly to be no better than if simply of cast iron, probably were not nearly as good as a well-made American chilled rim cast-iron wheel, and probably were in reality rather worse than the same cast wheels would have been *minus* their wrought-iron bones. It may be accepted as a fact, that no real accession of strength can be thus attained in any casting, if the cast iron be good soft gray or mottled metal; inasmuch as the extension per ton per inch of such, is actually greater than that of wrought iron for the first ton or two, so up to that limit at least the whole strain will come upon the one material only, helped by the slight surface adhesion of the two. Both materials also are in a state of initial strain more or less, dependent upon their diverse coefficients of contraction and their differences of temperature at the instant of consolidation of the cast iron. If, again, the cast iron be rigid and harsh, white or chilled or light mottled iron, then the whole strain is one of the two; and so these wheels, if made hard enough to have a tolerably well-wearing rim or tread, might break all to pieces, and all that the wrought-iron skeleton inside could do would be more or less imperfectly to hold the fragments loosely together. A remarkable and not uninstructive example of this was seen in 1867 at Paris, at the Great Exhibition contest between the bank safes of Mr. Herring and Mr. Chatwood.

The former maker fills the space between the outer and inner wrought-iron or steel plates of his safes with a plate of intensely hard Franklinite iron, poured in while in fusion. This is so hard that it cannot be drilled by ordinary means, but it is also extremely brittle, more so, apparently, than any ordinary white or chilled iron. As an alleged remedy for this, the Franklinite was cast upon or around a sort of network of tough wrought-iron cylindrical rods of about $\frac{5}{16}$-inch diameter, and it was affirmed that these conferred upon their hard and brittle surroundings their own toughness. When, however, plates of this combined material were broken up, which a few blows from a heavy hand-hammer were enough to effect, they proved just as brittle as ever. The dislocated fragments, it is true, or some of them, hung together, though more or less separated, by means of the reticulation of tough wrought-iron wires, and whose toughness did not in this instance seem to have suffered much change; but the plate as a whole broke up readily as before, and admitted of fragments being beaten out of it.

In Mr. Kirkaldy's museum at his testing works, Southwark, is a heavy cylinder of cast iron of very fine quality, in the middle of which is seen a very heavy concentric cylindrical bar of rather rigid wrought iron, cast into it. The original proprietor of this notable compound bar, of whom we know nothing, it appears brought it to be tested, and requested that the proof should be only carried up to some few tons per square inch, the allegation being that the cylinder was of some secret and improved *cast iron*. Arrived at this limit, the extensions appeared so strange to the experienced eye of Mr. Kirkaldy, that he resolved to go on *à l'outrance*, and so broke or pulled the cylinder in two, when, to the disgrace of some "person or persons unknown," the big wrought-iron bar was discovered in the middle. It was *this* bar, in fact, that was bearing nearly all the strain for the first few tons, and the cast iron when broken showed itself no better than common. It was creditable to the experimenter to have thus detected a disgraceful attempt at a *quasi* scientific fraud, but, besides the moral, we may draw also the physical lesson which we have been otherwise inculcating, from the result.

We thus may take it for granted that no increase of resistance, of any industrial value, at least, can be secured by trying to combine cast iron and wrougt iron or steel, by casting in, or one within the other. The advantages of casting in are limited, in reality, to economy, rapidity of execution, and convenience. We shall see that incidentally, however, in the case of wrought-iron structures, such as iron railings, or, as our French readers will better understand, *grilles*, certain additional advantages are secured.

The two following examples will at once illustrate the methods of practically employing the "casting in or on" process, and point out two of the chief classes of manufactured objects to which the process may with most advantage be applied. We shall take, first, the patent secured some years ago by Mr. David Moline, for a method of producing window sashes or frames by combining wrought iron with cast iron. The "muntins" of these sashes are formed of rolled wrought-iron bars in any of the usual rabbated sections fitted to receive the glass. These are cut or shorn off into appropriate straight lengths, equal nearly to the straight (or curved) sides of the panes. An iron pattern moulds the entire sash in the sand; when it is withdrawn, these straight pieces of iron sash-bar are laid into their respective places in the sand mould so that their ends approximate, four such coming together at each intersecting point, if the sash have square or rectangular panes. A boss or *patera* is moulded at each such intersection, ornamented or not, but of sufficient size to embrace the four disconnected ends of the wrought-iron bars, and when cast in iron, to solder or unite these together into one. These bosses are then "poured," either simultaneously by the aid of a compound "runner," or one or more at a time; the sash is then complete, all the loose pieces of "muntin" being so united together. They are extremely strong, may be made very ornamental, and have immense advantages, both in manufacture and in use, over the older sashes wholly of cast iron, in casting which it was always extremely difficult to preserve a light and large "muntined" sash free from bending, distortion, or fracture of some of the "muntins" while cooling, and the whole affair, if large, was so fragile as to scarcely bear transport, and to offer no resistance to violence.

The older and wholly wrought-iron sashes, on the other hand, in which the "muntins" intersected, and were united by "halving" or riveting to each other, were neither neat nor cheap.

Excellent examples of these improved sashes may be seen in the windows of the Ludgate Hill Station buildings of the London, Chatham and Dover Railway Station, in the front of the new Covent Garden Theater, and in many other places in London.

Casting wrought-iron pieces together in this sort of way is plainly not confined to the production of sashes. In fact, it has been employed, with excellent effect, by Mr. Thomas Page, C. E., in the production of two or three different classes of wrought-iron trellis railing, or fence, at the Chelsea Suspension Bridge, London, and its use in this direction might be largely extended with advantage.

The other example to which we shall refer is that of the grand line of *grille* or railing which extends for about 1,600 feet in a straight line, and forms the northern side of Nassau street, in Dublin, separating that from the park of Trinity College. This was designed by and executed under the direction of the writer. It consists of a succession of cast-iron perforated pilasters, of ornamental open work and work in relief, with caps and bases, and sustained by two scroll struts at the rear, at intervals of about 50 feet. These are "cramped," *i. e.* run with an alloy of lead and zinc, into the granite continuous base. The spaces between these are filled up by the *grille*, consisting of a flat wrought-iron horizontal top and bottom bar, each in one length, of upright round bars of wrought iron, and of cast-iron ornaments cast on to the same, which here form structural parts of the work.

In the production of this large quantity of railing, not a single piece of wrought iron was ever heated or put into the smith's fire. The top and bottom bars were rolled to the right length, and punched cold—the top one with $1\frac{1}{4}$-inch holes, all to let the vertical bars pass through them; the bottom one with five successive holes of $\frac{7}{8}$ diameter, and then one of $1\frac{1}{4}$ diameter, alternately. The round bars were ordered in two different lengths, five-sixths shorter (about $7\frac{1}{2}$ ft.), and one-sixth of them longer. Every sixth vertical bar passes through both the top and bottom horizontal bars, and for nine inches into the granite base, into which it is zinco-leaded, the lower end of the vertical bar passing through a hollow cusp, or foot-block, upon the top of which the bottom bar rests. The shorter bars are riveted cold through and at the bottom side of the lower horizontal bar, and pass through the upper one.

All the vertical bars being prepared and straightened perfectly by hand, the one-sixth longer being mere round bars of the proper length, and the five-sixths shorter with the bottom and neck collars, were then laid into sand moulds, in batches of twelve in one "box;" and the bottom and top ornaments, being moulded from hollow iron patterns, made to fit the wrought-iron pattern bars, and to keep their proper places and relative distances by means of steady pins, were then "cast on" to them. The top ornaments and then the bottom ones of each batch of twelve bars were "poured" simultaneously, and the sand was at once stripped off; the bars being all separately taken out, and the thin "gates" knocked off, which was all the dressing these ornaments required, or, indeed, admitted of; for though cast from soft gray pig, they were, by reason of their small relative volume, quite chilled through. Very few broke in cooling; very few were bad castings—and these were broken off from the bar by a blow or two of a hammer, and again others cast on. The hollow or open (as to design) halbert heads which complete the railing at top, were cast in green sand, and cored to drop on loosely to the top ends of the vertical bars, and so admit of being zinco-leaded on to the same.

Now, to erect this railing, the vertical bars were put into position, with the bottom horizontal bar, all laid flat into a wooden framing made to keep them in position and to clamp them so, until the whole sheet was hoisted into place. All the bottom ends of the collared bars were then riveted to the bottom horizontal bar. The "cusps" being in place over the holes "jumped" into the granite base, the whole sheet and frame was hoisted up by two tackles, and the longer bars dropped through the "cusps" into the holes in the base, the ends of the horizontal bar being inserted into the mortices in the pilasters, in which they were held fast, though free to expand and contract within these. The top horizontal bar was then dropped over the tops of the vertical round bars, until it rested upon the uppermost part of the top "cast-on" ornaments. The halbert heads were then dropped over the projecting tops of the vertical bars; the vertical bars, which were in the holes in the stone base, were zinco-leaded into same; the halberd heads were likewise so secured to the tops of the vertical bars, and then that length of railing was complete. A scroll rear strut corresponding with those of the pilasters was secured at the middle of each length, so that there are thus struts at every five-and-twenty feet, or thereabouts. If we have succeeded in making clear to the reader the processes followed, he will have recognized how small was the amount of workmanship expended in the production and erection of this railing. In reality it did not, upon the wrought-iron portion, amount to more than about 40s. per ton of the material.

The entire economy here was due to the application of the method of "casting on," for that alone permitted of all the other structural details being carried out.

One great advantage resulting from this method of construction is the possibility of dispensing with "leading on" the cast-iron ornaments as commonly practiced. So put on, every lead collar is an electro-negative galvanic element, increasing the tendency of the iron to rust, and causing the corrosion to be local and locally powerful. With many designs it would be practicable to dispense with the use of "cramping" or leading altogether. With that we have described this might have been done, at a little greater expense.

The writer, however, had proved experimentally that an alloy of zinc and of lead may be formed, whose galvanic relations to iron are much more nearly those of zinc itself to iron, than those of lead to that metal, and in fact such as not to cause any fear from its local increase of corrosion on the iron of railing. This alloy he adopted in place of lead, for what he has called the zinco-leading or "cramping" together, and the result has justified his experimental previsions, for after twenty-six years, and not more than four coats of dark green paint during the time, there are no signs of local corrosion whatever. Zinc itself would be best of all as a "cramping" metal, but it runs too thick and drossy to form a close or safe junction.

In some ornamental railing recently erected at Westminster, the uprights are secured without leading to the granite, by iron studs and screws and by Portland cement. This is, however, a bad plan; one may say "out of the frying-pan into the fire," for the bond of the thin plate of Portland cement is certain to be broken by the expansion and contraction of the metal, and then water will find its way in by capillarity, rust will form between, this will, as usual, expand in volume as compared with that of the metal from which it has been produced; and the railing will be lifted up or the base claws broken by it, or by the expansion of water frozen between the joints which it shall have entered.

The points upon which we have here been treating are wholly those of the practical ironfounder, and of the founder in one of his humblest capacities, namely, as the servant of the architect and builder. It is to be hoped that enough has been put before the reader interested in the founder's art, however, to impress upon his mind the advantages he may occasionally derive from the method of "casting on," and to indicate the cases in which and why it should be shunned, and also some of those in which it may be employed with a value and profit proportionate to the skill devoted to its special adaptation.

HISTORY OF DECARBURIZING IRON.

No. V.

MALLEABLE IRON AND STEEL SCRAP AND CAST IRON MIXED AND PUDDLED—ALSO ALLOYING OTHER METALS WITH IRON.

STIRLING, JOHN DAVIE MORRIES.—1848. October 12. No. 12,288.

"Improvements in the manufacture of iron and metallic compounds." The patentee, after referring to his letters patent of June 29, 1846 (see No. 11,262), describes his improvements in the manufacture of malleable iron and alloys of iron and other metals. 1st, in making malleable iron, he adds malleable iron scrap in proportion of from $\frac{1}{20}$ to $\frac{1}{5}$, or even $\frac{1}{4}$ by weight to white pig iron in the pig bed, or otherwise, and the mixture is then boiled and puddled so as to thoroughly incorporate the whole together. Another mode of mixing, which is preferred, is to melt the malleable and cast iron in a suitable furnace, and then run the liquid mixture into the puddling furnace; the expense of refining iron is by these processes avoided. If good qualities of cast iron be employed, larger proportions of malleable iron should be used. Refined iron may, if required, be also combined with malleable iron scrap. Steel scrap also improves the quality of the iron. To produce an alloy of malleable iron less fibrous and harder than the common iron, block tin or groin tin may be added in proportion of from $\frac{1}{200}$ to $\frac{1}{100}$ by weight to any of the above mixtures; bismuth, antimony, and arsenic may be similarly used, and also zinc and copper, which produces a hardening effect, and manganese, which gives a steely character to the iron. An alloy of zinc and iron is produced by introducing zinc into the cupola furnace when the charge has been lately run out; the zinc combines with the iron left adhering to the sides of the furnace, and forms a mixture which should contain from 4 to 5 per cent of iron; if it be found to contain less more iron should be added. The specification also describes a method of making an alloy resembling gold from zinc, iron, copper, and manganese, which is called British gold; also an alloy of copper and manganese; also an alloy of zinc, iron, and copper, and nickel, and manganese resembling silver.

[Printed, 5d. See "Repertory of Arts," vol. 16 (enlarged series), p 42; "Artizan," vol. 7, p. 231; "Patent Journal," vol. 7, p. 12; "Mechanics' Magazine," vol. 50, p. 381.]

ORE AND SCORIA MOULDED INTO BRICKS FOR PUDDLING FURNACE LINING.

WILLIAMS, GEORGE.—1849. January 13. No. 12,416.

"Improvements in preparing puddling furnaces used in the manufacture of iron." Iron ore and scoria are ground to powder and mixed with water, so as to form a kind of paste. This is moulded into bricks or slabs or other suitable shapes, dried and baked, and used as a lining for the sides and bottoms of furnaces.

[Printed, 6d. See "London Journal" (Newton's), vol. 35 (conjoined series), p. 19; "Mechanics' Magazine," vol. 51, p. 66; "Patent Journal," vol. 7, p. 173.]

PUDDLING FURNACE WITH TWO CHAMBERS; AIR AND STEAM JETS IN PUDDLING.

PLANT, REUBEN.—1849. July 18. No. 12,706.

"Improvements in making bar or wrought iron." The object of the invention is to regulate the heat during the process of puddling iron. A puddling furnace is described having two chambers, a puddling and a preparatory chamber, with a damper between them. Hot or cold blasts of air and jets of steam are used, as described, for regulating the heat in the chambers respectively.

[Printed, 9d. See "London Journal" (Newton's) vol. 36 (conjoined series), p. 173; "Patent Journal," vol. 8, p. 212; "Mechanics' Magazine," vol. 52, p. 61.]

AIR HEATED BY THE BRIDGES AND SIDES OF A FURNACE AND FORCED INTO ITS CLOSED ASHPIT.

PRIDEAUX, THOMAS SYMES.—1849. August 30. No. 12,750.

"Improvements in puddling and other furnaces."

Firstly, a puddling furnace is described having a closed ashpit to which air is supplied under pressure. The air is conducted through pipes or passages regulated by cocks or valves under the bottom of the puddling furnace and through the bridges, so that it becomes heated, and the sides and bottom of the furnace and bridges are cooled. The heated air is thus forced into the closed ashpit, and introduced into the furnace, or it may be introduced through openings in the sides of the furnace.

Secondly, a smelting furnace is described, having a fireplace in the front, and behind that a kind of crucible, and behind that a smelting chamber into which the ore is introduced through a hopper. The smelting chamber communicates with a chimney. Air is forced through suitable passages formed in the brickwork of the lower part of the furnace, and is supplied in a heated state, and under pressure, to a closed ashpit, and thence introduced into the furnace.

[Printed, 10d See "Repertory of Arts," vol. 16 (enlarged series), p. 25; "Mechanics' Magazine," vol. 52, p. 194; "Patent Journal," vol. 8, p. 270.]

PUDDLED STEEL—ALSO, DECARBURIZING CAST IRON BY HEATING IT ENVELOPED IN CLAY, AND BY PASSING AIR OVER IT WHILE HEATED.

RIEPE, EWALD.—1850. Jan. 29. No. 12,950.

"Improvements in the manufacture of steel." These consist, firstly, in a peculiar manner of working the puddling furnace. A charge of about 280 lbs. of pig iron is introduced and raised to a red heat, when the fluid begins to melt the damper is partially closed to lower and regulate the heat. Twelve or sixteen shovelsfull of slag or cinder iron are then added, and the whole melted down. The mass is then puddled with a little black oxyde of manganese, common salt, and dry clay ground together. After the mixture has been acted on for some minutes the damper is fully opened, and 40 lbs. of pig iron (or if the ore be sparry iron ore, 20 lbs.) are added, and melted with the charge at a cherry-red heat; as to this part of the process minute directions are given.

Secondly, pig or alloys of pig and wrought iron are cast into thin bars $\frac{1}{4}$ to $\frac{3}{4}$ inch in thickness, these are enveloped carefully in best plastic clay and heated in a furnace for from one to three days, until they are converted into steel. A suitable furnace is described for this process.

Thirdly, the iron bars cast as above described are placed in a cylinder made of fireproof stones so as to allow a stream of atmospheric air to pass through and touch freely all the bars. The cylinder is bricked up at the end, as described, and the bars heated until they are converted into steel.

[Printed, 7d. See "Repertory of Arts," vol. 16 (enlarged series), p. 222; "London Journal" (Newton's), vol 37 (conjoined series), p. 175; "Mechanics' Magazine," vol. 53, p. 98.]

MAKING STEEL BY MELTING ORE, STEEL AND WROUGHT IRON TOGETHER.

ONIONS, WILLIAM.—1851. February 7. No. 13,496.

"Improvements in the manufacture of steel." These consist in melting certain matters together and running the product into castings directly, and then annealing them. Two parts by weight of hematite ore with four parts by weight of common steel, and 94 parts of iron made from Cumberland or other like ores, are placed in a crucible and melted. The metal, instead of being run into ingots, is run at once into moulds of the required shapes. The castings are then annealed, and are so rendered malleable, when they may be treated in like manner to articles made of ordinary steel. The annealing is carried on in like manner to that resorted to in annealing articles made of cast iron from Cumberland and similar ores, whereby they are rendered malleable. Articles like bars, about an inch square, should be raised to a red heat in 24 hours, and maintained at that heat for about 120 hours, and then gradually cooled. Cast-steel articles so made may be cut or dressed or partially formed and tempered like articles made of ordinary steel.

[Printed, 3d. See "Repertory of Arts," vol. 18 (enlarged series), p. 331; "London Journal" (Newton's), vol. 39 conjoined series), p. 344; "Mechanics' Magazine," vol. 55, p. 136; "Patent Journal," vol. 11, p. 231.]

NOTE.—*The effect of the small percentage of ore must be to slightly decarburize the iron and steel.*

PIG IRON BOILED WITH ORE AND CARBONACEOUS MATTER MIXED, COOLED IN A SPONGE, GROUND, ASSORTED, REHEATED AND BALLED.

HAZLEHURST, ISAAC.—1851. June 3. No. 13,655.

"Improvements in the manufacture of iron." These relate to the puddling process. The iron is puddled in the furnace with a mixture of iron ore and carbonaceous matter, as ground coal, coke, charcoal, or sawdust. When the iron is puddled the damper is to be lowered until the metal begins to thicken, "it is then boiled and kept very hot until it becomes very thin or liquid." The draught is then "checked until the metal is brought into a state" ready "to ball." It is then drawn out in convenient size, but "without being balled, and placed in a closed barrow, or other receptacle" made to exclude external air, and left to cool. It will then be in a spongy or honeycomb state, and is to be crushed or ground by stampers or rollers; the bad or imperfectly worked iron must be picked out, and as much good iron as will make a bloom is put in a furnace and balled at a low heat, and worked under the hammer or squeezer in the usual way. The iron so made does not require cutting and piling, and is suitable for spades, edge tools, boiler plates, wire, &c. If required to take a polish, the crushed or ground iron should be scoured. The ground iron is also used "for sinking in the charcoal fires, for making iron for conversion into steel," instead of charcoal pig or best scrap iron.

[Printed, 3d. See "London Journal" (Newton's), vol. 30 (conjoined series), p. 282; "Mechanics' Magazine," vol. 55, p. 495; "Patent Journal," vol 12, p. 121.]

FRANKLINITE USED IN THE PUDDLING FURNACE.

JONES, S. T.—1851. September 16. No. 8,357. (U. S.)

CLAIM.—The application of Franklinite to the improvement of iron in the processes of reduction from its ores, and in the finery or puddling of crude or pig iron, according to the methods as above described.

CHROMIUM—ALSO SALT, BARYTA, LIME AND SODA—USED IN THE PUDDLING FURNACE.

STIRLING, JOHN DAVIE MORRIES.—1851. December 22. No. 13,877.

"Certain alloys and combination of metals." This invention is an improvement on that patented by the inventor on January 31, 1851. See No. 13,486. It relates to coating metals, such as iron, copper, tin, &c., with metals and metallic compounds, as tin, copper, zinc, lead, gold, platinum, &c., and their alloys.

Also in improving the quality of iron by adding chromium, by preference, in the condition of chrome iron, or chromate of iron, in proportion of from $\frac{1}{400}$ to $\frac{1}{800}$ of each puddling charge; or it may be added at an earlier stage than the puddling process. When the iron is particularly cold-short or red-short a chloride is added, and common salt, at the rate of $1\frac{1}{2}$ to 3 lbs. to each charge. The chromate is to be added when the iron is nearly or quite melted, and the softer iron takes more than the harder class.

Also, instead of chromium, baryta, or its salts, by preference, the carbonate may be added to iron, 1 lb. of carbonate to each charge in the puddling furnace.

Also carbonate of lime and muriate of soda, in equal proportions, may be advantageously added to the iron; from 2 to 3 lbs. of the mixture being added to the puddling charge.

NOTE.—*The patent also specifies using lead and chlorides in the blast furnace.*

PUDDLING—THE FIRST PERIOD WITHOUT STIRRING. THE PRODUCT MELTED WITH EXCESS OF CARBON AND REMELTED WITH IRON TO DILUTE THE CARBON.

COLLINS, WM. WHITTAKER.—1852. March 24. No. 14,033.

"Improvements in the manufacture of steel." A communication.

A charge of about 4 cwt. of grey pig iron is "melted in the puddling furnace in the ordinary way, with a large quantity of silicate of iron or other metallic oxyde." The first period of the boiling process is continued without "stirring or raking the metal," as is ordinarily done. The melted mass is thus left quietly exposed to great heat, "by which means the impurities, less the carbon, are burned." This process is continued for from 15 to 30 minutes, according to the nature of the iron. The iron will then begin to rise up, and must be then worked vigorously "under the action of the highest degree of heat," to make it fit, as soon as possible, to be balled up for the hammer or squeezer or rolls.

The product will be pure "close-grained iron," which "either in the state of milled bars, balled iron, or finished bars, will unite with facility with various proportions of carbon." They are, therefore, without previous cementation, "melted in crucibles, with the application of carbonizing substances, by which means cast steel is produced," of which the degree of hardness "may be regulated by the application of carbonizing substances in greater or less quantity."

"A superior quality of cast steel adapted for tools, chisels, &c., is obtained by melting the said bars with a comparatively large proportion of carbonizing substances." The product is a highly carbonized brittle cast steel. "This is to be remelted with fresh parcels of the said iron bars."

[Printed, 3d. See "London Journal" (Newton's), vol. 41 (enlarged series), p. 317; "Mechanics' Magazine," vol. 57, p 279.]

DECARBURIZING CAST IRON BY HEATING WITH OXYDE OF ZINC OR LEAD, TO MAKE BARS WITHOUT PUDDLING.

BEAUVALLET, JEAN ERNEST.—1852. June 12. No. 14,167.

"Improvements in the manufacture of iron and steel. A communication. These consist in heating cast iron "in contact with a metallic oxyde (or it may be "a carbonate which will act by reason of its oxyde)," and afterwards extending it by hammering or rolling, without the necessity of puddling it. Directions are given as to the way in which the iron is to be cast in bars or sheets, so that the impurities and bubbles may form their ends, and be cut off with the rough ends of the sheets or bars.

For the decarbonization of cast iron protoxyde of zinc and calamine are preferred, but oxyde of lead may be used. A table of proportions is given. The zinc, if any remain, is to be driven off by heat. When malleable iron is to be made, much of the decarbonizing substances must be employed; when steel is to be made less will be required, but the steel should be cemented with charcoal in the ordinary way, to expel the zinc and equalize carbonization.

[Printed, 4d. See "Repertory of Arts," vol. 20 (enlarged series), p. 363; "Mechanics' Magazine," vol. 57, p. 497.]

HARBOR DEFENSE—FLOATING GUN-CARRIAGES.*

BY SIR WM. G. ARMSTRONG.

From the London "Times."

Sir Wm. G. Armstrong calls attention to the value of small vessels (like the "Staunch," designed by Mr. Rendel), for defending seaports against the sudden inroads of hostile ironclads in time of war. The importance of protecting commercial harbors from this kind of attack is a subject which deserves more attention than it appears to receive. The intrusion of an invulnerable war-ship into the port of Liverpool, for example, is alarming to contemplate. Masses of merchant ships closely packed in docks, and large stacks of warehouses containing merchandise worth millions, are objects upon which the powerful shells of modern artillery would produce terrible effect. To prevent the ships of an enemy from approaching our shores would require our fleet to be ubiquitous, and if hostile ironclads cannot be kept at a distance, there is nothing at present to stop them from entering our ports. The experience of the late American war shows that it is very difficult to intercept a steam war-ship on the open seas; and under present circumstances it is certainly presumable that, whether we should happen to quarrel with the United States or with an European power, vessels would be fitted out on the other side of the Atlantic for inflicting every injury upon our property and commerce.

Let us consider, then, what is necessary for the defense of our seaports. We may presume that the kind of vessel which would be used for making a dash at a harbor would be a steamer large enough to unite speed and sea-going qualities with the protection of heavy armor. She would carry guns of great size, adapted alike for engaging and opposing ironclads and throwing enormous shells. She would be rendered secure against boarding, and be protected against small arms. Without heavy rifled guns no impression could be made upon such an enemy as this, and of such guns there are none in any one of our commercial harbors. Supposing, however, the guns to be forthcoming in time of need, we have still to consider how they can be most advantageously applied. We have, in fact, to choose between mounting them on fixed or floating platforms. If we plant them as fixtures, the batteries containing them must be at points where the channel can be commanded within easy range, and where a boom or other obstruction can be thrown across to detain the invader under fire. Without such detention, the time occupied in running past a battery is too short to admit of decisive results. The rapid motion and constantly varying distance of the vessel would make it difficult to hit her in a vital part, even if cool deliberation and judgment were used; but the difficulty would be enormously increased by the hurry and excitement that would prevail among the gunners during the brief passage of an enemy's ship. There is, however, this objection to booms and similar obstructions, that they cannot be so contrived as to be capable of stopping an enemy without at the same time interrupting commercial traffic. Nor is their efficacy as a barrier certain, since it is hard to say what steam an iron cannot break through. So that, altogether, the method of protecting harbors by batteries and booms is not very promising. If we now turn to the other alternative of using the guns afloat, we shall find that the difficulty vanishes. The vessels for carrying the guns need be nothing more than floating gun-carriages, like the little Staunch. This vessel, though a mere barge in point of size, carries a $12\frac{1}{2}$-ton gun, the movements of

* The idea of floating gun-carriages, as here referred to, though well carried out in England, is not of English origin. The "Naugatuck," built by the late E. A. Stevens, and fought in the late war, was merely a floating gun-carriage, the gun (100 pr.) being trained by turning the vessel by means of twin screws. See "Ordnance and Armor," p. 591—ED. *V. N. M.*

which are effected by steam-power, so that a very small screw suffices for working it. The boat is propelled by twin screws, which give her such a power of turning that she can change the direction of her large gun as easily and quickly as if it were mounted on a turn-table. She is incumbered with no armor, because her safety lies in her smallness, which renders her difficult to hit, and because armor is worse than useless when opposed to guns capable of piercing it. Finally, she is cheap. The cost of a couple of ironclad frigates would furnish a hundred Staunches.

Now, to revert to Liverpool as an example, let us see what would be the aspect of the case if half-a-dozen of these gunboats were at hand when an enemy's ship ran into the Mersey. She would there find herself surrounded by six little dots upon the water, carrying among them an armament probably even heavier than her own. They would be so small that she could not well hit them, while she would be so large that they could hardly miss her. She could not run them down, for they would be far too quick at turning, and a retreat under shallow water would always be open to them. If by a lucky shot the enemy were to sink or disable one of her assailants, it would be but one silenced out of six. She, on the other hand, would be equally liable to be sunk or disabled by a single shot, so that the chance of victory would be six to one against her, even if she were as difficult to hit as her adversaries. In short, six such gunboats would probably suffice to baffle the attack of several ironclads, and we might be very sure that no hostile attempt would be made to enter a harbor where it was known that these dangerous watchdogs were kept.

Nor is it merely their mobility within the area attacked that recommends these little vessels. The Staunch has proved herself an excellent sea boat both with her gun on deck and in the hold, into which it can be lowered at pleasure by her mechanism and again raised when required. Such vessels, therefore, could quickly be brought from different ports to any point attacked. Moreover, they would constitute excellent schools of gunnery for the naval reserve men, who might in them, at small cost, gain valuable experience in handling heavy guns. Indeed, I should not despair of a class of naval volunteers being established capable of managing such gunboats, and thus rendering every port self-protective. Again, if we are to contemplate the possibility of aggressive war on our part, these vessels will be quite capable of crossing a sea in company with suitable tenders, and would thus be available for foreign service in case of need, or they would prove valuable auxiliaries for the defense of our naval arsenals, if threatened with attack. When not in use they would be laid up on slips, almost free of cost for maintenance, and they could be lanuched, armed and manned at very short notice.

In offering these brief suggestions on the subject of harbor defense I do not wish to ignore the great value of torpedoes as aids in guarding the entrance of a port; but these implements cannot be looked upon as superseding the use of artillery for that purpose. Even with the best arranged system of torpedoes, it is not difficult to conceive a mode of attack by which the defenders might be deceived either into exploding them prematurely or upon comparatively valueless ships sent in for the purpose; and once exploded, a new system could not be laid down in the presence of the enemy. In fact, there is no knowing what expedients might not be resorted to for evading or neutralizing their effects. For my part, I am persuaded that nothing would prove so free from objection as small gunboats with big guns. But, whatever difference of opinion there may be as to the best mode of attaining the object, certain it is that at the present time we are prepared with nothing that would have the least chance of proving effectual.

In conclusion, I would observe that the preference I have expressed in favor of guns afloat over guns in fixed batteries has reference altogether to commercial harbors, and does not apply to great naval stations like Portsmouth or Plymouth, where much more powerful defenses are required, and where a combined system of fixed and floating batteries would probably be necessary.

NOTES ON RAILWAY CONSTRUCTION.

BY W. AIRY.

From "The Engineer."

It may fairly be said that in England there are scarcely two railways alike; the country is so diversified and irregular in its outline, and so varied in its soil and geological character, that there can scarcely fail to occur, in the course of the construction of a railway, difficulties peculiar to that railway. Such difficulties may not have been of such importance as to form the subject of a separate memoir, but they are, nevertheless, important to those who are engaged in such work, and if carefully recorded by the engineer in charge, they would form a most valuable mass of information, and from which a book on railway construction could be compiled far more trustworthy than any work compiled only from theory, or the limited experience of a single individual. For the publication and circulation of such notes there would seem to be no more proper or convenient channel than the columns of the best engineering papers of the day, in which they would be preserved for reference. In the following notes the writer does not profess to confine himself to what may be novel in the methods he adopted, but to record the methods themselves, and the experience gained in the application of them.

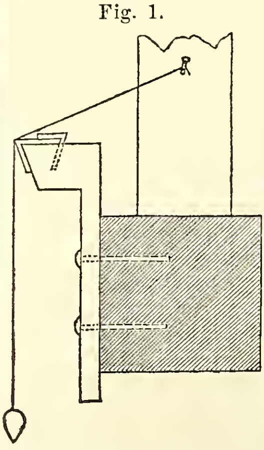
ON SETTING-OUT IN TUNNELS.

There is no ordinary field work so anxious or careful as that which occurs in the steering and setting out of a long tunnel. The chances of error in transferring lines and levels from the top to the bottom of a shaft are considerable, and the carrying on of them properly below ground is also liable to error, from the darkness and the shortness of the base from which to produce the line of the tunnel onwards. Now the accuracy needed in transferring the line of the tunnel from the top to the bottom is according to the number of the shafts; if the shafts are very close together—say, for instance, 100 or 200 yards apart, as they commonly are—the accuracy needed is not exceedingly great, but in proportion as the distance between the shafts increases, so also does the accuracy required, and when, as rarely happens, the shafts are as far apart as 700 yards, the accuracy needed is very great.

In the instance now recorded, a lofty range of hills, which was pierced by the tunnel, precluded the use of numerous shafts; the distance between two of the shafts was more than 700 yards, and in consequence of great difficulties, arising from the quantity of water encountered, the work was much hindered at one of these shafts; so that more than 600 out of the 712 yards between them were pierced from the other shaft, which was comparatively unincumbered with water, before the headings met. For the ranging of this length of 600 yards no method presented itself so practicable as the ordinary process of suspending two lines from the sill of the shaft in the line of the tunnel, and carrying on the line of the heading from the direction so obtained. But as the shaft was only 9 ft. in diameter, and the net distance obtainable between the two lines, so as to allow them to hang perfectly clear of obstructions of all kinds, was only 6 ft. 6 in., it was obvious that unusual care must be taken in the production of so long a line on so short a base. Had the tunnel been straight from end to end, it would have been safer and less troublesome, in this instance, to have ranged the line from the open end, where the heading emerged; but there happened to be a sharp curve at both ends of the tunnel, which would have rendered this method uncertain and indirect.

Now to arrange a line accurately below ground, by means of a pair of lines let down a shaft, it is necessary, first, that the lines should be accurately adjusted at the top; and, secondly, that the direction of the tunnel should be accurately produced from the direction indicated by the lines as suspended. In the instance in question the adjustment at the top of the shaft was managed thus: The center line of the tunnel being truly ranged above ground by the ordinary process, a station on the line was established and carefully marked at a few yards' distance from the shaft; a theodolite was placed over this station, and adjusted so as to range the true line of the tunnel. On each side of the shaft, and in the line of the tunnel, a board, of the shape shown in the figure, was firmly nailed to the sill of the shaft; this board was furnished with a movable nosing of iron, which was tightly clipped down upon the board by iron clips, so as to be firm and secure from shifting, yet capable of adjustment along the nose of the board by tapping lightly at the ends with a hammer. A small notch was filed on the edge of the nosing to receive the plumb-line. The nosing being roughly adjusted to the line of the tunnel, and the plumb-line passing over the notch and down the shaft, the observer at the

Fig. 1.



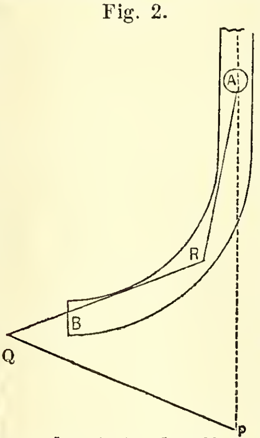
theodolite indicated the true position of the notch to an assistant at the board, by whom the iron nosing was gently tapped with a hammer till the notch and plumb-line were together brought into the true center line of the tunnel. The same was done at the other side of the shaft, and the adjustment at the top was then complete. In this way it is seen that a very high degree of accuracy was obtained, with great security and freedom from accidental shifting of the lines. The plumb-lines were of very strong and fine fish-line, and the plumb-bobs suspended in buckets of water at the bottom of the shaft in the usual manner.

For the production of the line of the tunnel below ground, the following plan was adopted: A stout deal table, on three legs strongly framed together, was firmly planted in in the line indicated by the plumb-lines, and at a distance of about eight yards from them; on this table was placed a theodolite, properly furnished with a lamp for illuminating the wires; this theodolite was placed roughly in line, and adjusted level by the foot-screws. The nearest plumb-line was then illuminated by two men with candles, and the theodolite was pointed so as to bisect that plumb-line, and was clamped fast. The two men then left the front plumb-line, and in like manner illuminated the back plumb-line. This line would appear in the telescope to one side or the other of the intersection of the wires, and the theodolite was shifted on the table to one side or the other, as was indicated by the observation. The whole operation was then repeated anew, and continued until, by successive approximations, the telescope was so truly adjusted to the line indicated by the plumb-lines, that after it had been directed so as to bisect the front plumb-line, the back plumb-line, on being illuminated, remained invisible from the obstruction of the former. Having thus obtained the true line of the tunnel, and carefully clamped the theodolite, the telescope was turned in a vertical plane, and candles were ranged by signal at such distances along the heading as were necessary, and permanent marks established at fixed places for reference.

It may not be uninteresting to know the degree of accuracy which may be insured by the above process. In order to eliminate all chance of accidental error, the work was done three times over from the beginning, at intervals of a month, and on each occasion a permanent nail was fixed in the line ranged at ten chains distance from the shaft. The three nails were driven side by side, and the distance between the two outside nails was $3\frac{1}{2}$ in., thus the limit of error at 30 chains' distance from the shaft would be less than 1 ft. The actual error, as was proved when the headings met, was less than 1 in.

As a check upon the above process, the following plan was used after the heading at the end near the shaft had been driven through to daylight. It is evident that the accuracy of this method depends much upon the number and position of the stations, which the curve renders necessary, as also on the size of the heading, etc.; but it may in some cases be found practicable and useful. Let A B be the heading, A the shaft, and B the open mouth of the heading. Let A P be the line of the straight portion of the tunnel as ranged on the ground, P a station on that line. Take a station at Q, near the mouth of the heading, from which P can be seen, and a station inside the heading at R, from which Q can be seen, and more stations if necessary, until A (a station vertically below the center of the shaft) can be seen; measure by theodolite all the angles A P Q—P Q R, etc. Then, since the fig. A P Q R—A is a closed figure, and all the angles are known except the last angle (in the figure it is P A R), this angle also can be determined. Therefore, planting the theodolite at A, pointing the telescope in the direction A R, and setting off the angle R A P, determined as above, the direction A P is obtained; and by turning the telescope in a vertical plane, the line of the tunnel, supposed in the direction of P A produced, may be ranged with considerable accuracy.

Fig. 2.



There is no great difficulty in setting out the levels of a tunnel. Leveling is such accurate work that an error at commencement does not seriously increase with the distance if moderate care be used. All that is necessary is to obtain pretty accurately the level of a bench mark at the bottom of the shaft; this may readily be done by tying two or more chains tightly together, the chains being first carefully measured, and suspending them from a nail in the sill of the shaft, the level of which is known; with these, and a level-staff to close in the measurement at the bottom, the level of a nail at the bottom may be ascertained to a quarter of an inch without difficulty. The levels may then be carried on by candle-light with great ease to the end of the heading in the usual way. The light of a candle, held near the object-glass of the telescope, though not so as to obstruct the view, is amply sufficient to illuminate the wires; and the staff, when lighted up, can easily be read at five or six chains distance, if the heading be not choked with smoke or otherwise obstructed.

ON THE MANAGEMENT OF CLAY SLOPES.

Very few railways exist which do not at some place or other pass through clay, either in the form of detached beds or pits, such as occur in all geological formations, or else as a recognized formation in itself; and there are no beds which give so much trouble in the construction and maintenance of railway cuttings, except perhaps the beds of running sand holding much water, which are comparatively rare. The varieties of clay beds are wonderful; in the experience of the writer there were found in the short distance of ten miles all kinds of clay, from black shaly clay, which would stand at a slope of 1 to 1 without slipping, to yellow greasy clay, which would barely stand at 3 to 1 (and which the slightest rain rendered very difficult to handle), and again to black rotten clay, which would not stand at 6 to 1, and indeed seemed unwilling to stand at any slope whatever. There seemed to be no principle of general application which ruled the nature of the clay, except that wherever water was present, the clay was worse to handle, and that clay on the sides of hills through which the drainage of the country had to percolate was worst of all. As a rule the clay of the earlier formations was firmer and better than that of the latter, and the black clay was better than the yellow; but the pitch of the ground and the position of the cutting would at any time affect the working of the clay very largely.

When, from the nature of the clay and the local circumstances of a cutting, it is apprehended that the slopes will not stand at the inclination originally intended, thero are various methods of proceeding which may be suitable for different cases. The chief of those which were tried in the case of the railway in question were as follows:

1. To get out the slopes to a flatter angle of inclination than was at first intended.

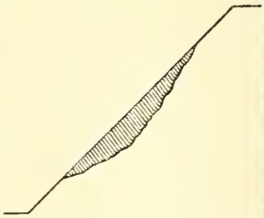
2. To get out the slopes with a curved batter, keeping the width across the cutting at the top the same, or nearly the same, as was originally intended.

3. To retain the foot of the slope by a low wall, and to flatten the remainder of the slope above the wall by taking stuff from the top of the slope and casting it down against the back of the wall.

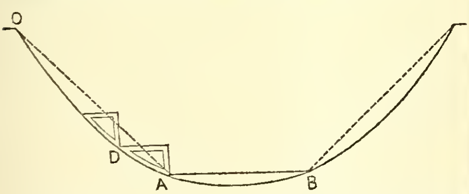
4. To drain the slopes, whether by bushes, rubble-drains, or pipes.

The first of these methods is the most wasteful of all; the labor required in getting out the slopes to a flatter angle is very great, and there is usually a necessity for purchasing additional land, which involves much expense and delay. Nevertheless, in exceedingly bad ground there is nothing else to be done, more especially if the ground be much charged with water, for then the slopes will not bear shaping. But this method will be much assisted by retaining the toe of the slope in some degree; a low wall of rubble-stone well hand-packed will keep a slope quiet at a comparatively steep angle of inclination, which would slip immediately and constantly without it, and give incessant trouble. The wall should be let into the ground to a depth of about 3 ft. below formation level, and if well laid and of good thickness, will save much money in maintenance; it should be of dry rubble-work, to give free passage to the water.

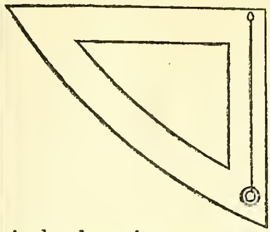
The second method is not commonly practiced, and is too much under-valued. It is rather more troublesome to get out slopes to a curved batter than to a straight one, and in consequence all gangers and workmen have a great objection to using this method; but it is the natural and stable form of the ground when laid to a slope, and the only correct form in which to leave it. In very good ground, which requires only a slope of $\frac{3}{4}$ to 1, or thereabouts, there is no great object in going to the trouble of making the slopes hollow; but as a general rule, a great saving might be effected by it, both in the first cost of the railway and in the subsequent maintenance. As regards the correctness of the above statement, it will readily occur to all who have had experience of railway slopes, that when a slip takes place in a straight slope, it rarely begins at the top of the slope; a wedge-shaped mass of stuff breaks out from the middle and lower parts of the slope, as in the annexed diagram, and slides down into the cutting; the top remains, sometimes overhanging, and, if not attended to, gradually crumbles away and falls down piecemeal.



Such an appearance suggests at once the proper shape to which a slope should be worked, and in one or two instances in the writer's experience the slopes were purposely and carefully worked to curved batters in the following way: The curve selected for the batter was the parabola. What the precise theoretical curve might be is not easy to ascertain, and the conditions of ground vary so exceedingly in different situations, that it would avail us little to know it for any precise case. It is something like a parabola, and as it was necessary to assume some curve or other, the parabola was selected, both as seeming suited to the case, and as being simple in its properties, more especially as regards its area, which is important as offering facilities for the calculation of the cubic contents of the earthwork. The principle on which the curve was applied will be seen from the diagram annexed.

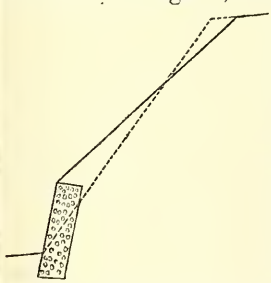


AB is the formation width of the cutting; A C the straight slope; A D C the parabolic slope; the constant of the parabola was so fixed that the two sides of the cutting, when completed, would, if produced underneath the formation, form the entire parabola; the object of this was that, as far as possible, the pressures of the two sides might balance each other without wedging up the formation between them, as sometimes occurs when the batters are straight. For the setting out of the slopes, two curved templates were made and applied as in the figure above. A draft was first traced



in the slope to the straight line A C; then the first, or lowest, of the templates was applied, and the draft deepened till the outside edge of the template was vertical; then the second template was applied, with its lowest angle at the point where the first template left off, and the slope in like manner dressed off till the outside edge of the second template was vertical. The slope being thus started true to curve, the rest of the draft could be completed with sufficient accuracy by eye, and the cutting got out between the drafts in the usual way. The above method is fairly simple and easy, and the cutting is far more secure than when the slopes are flat. This was curiously exemplified in one case where the slopes of a cutting had been dressed as above, except at two points where the batters were left straight from some accident; at both these points a slip took place in the following winter, while the rest of the cutting remained secure. As a general addition to the security of a cutting, this second method is the most correct, and involves the least expense.

The third method is very useful and convenient; the application will be seen from the annexed diagram, where the dotted lines



show the state of things as at first intended, and the full lines the amendment. The wall may be of any hard stuff, big and small together, except the face, which should be of large pieces, hand-packed. Chalk was found excellent for retaining the yellow clay, and the expense of such rough work is very insignificant. The great advantage of this method is that it involves very little, if any, removal of stuff in wagons, and the work can therefore be carried on without blocking the way. The wall should, if possible, be got in before the cutting has slipped much; if the slopes have slipped in, and the clay is much mixed with water, it is very difficult to keep the clay out of the wall, and to make good work.

With respect to the fourth method, so far as the writer's experience went, it is useless to attempt to save a cutting from slips by draining the slopes during construction. For the maintenance of completed railways it is, of course, necessary to allow free passage to the surface water; but for this purpose surface drains are sufficient, and the introduction of deep drains into clay slopes is in general most injurious; the deep drains do in fact, in most cases, lead the water into the body of the slopes, instead of keeping it out; the continuity of the ground is injured, and slips take place in consequence of the drains. Moreover, deep drains are very apt to get choked, especially when any slight motion is taking place in the cutting, and immediately a body of water collects, to the great injury of the slopes. The work of laying in deep drains is very costly, and in no one instance on the railway in question did it stop the progress of a slip for a single day; bushes, large rubble drains, and pipe drains were all employed, but without the least effect, and the slopes had either to be got out flatter, and the stuff removed in wagons, or retained by a rubble wall, according to the third method here given.

If different beds are met with, special methods must be used, as benching the slopes at places, which may sometimes be done to great advantage. The weak point of a cutting is the toe of the slope; it is usual to cut a grip on each side of the way to run off the water, and this grip often seriously undermines the slopes, and causes many slips. This may be to a great extent prevented by using pipes instead of open grips, and covering them over with loose stones, taking care also to provide gulley-holes to catch the dirt which drains into the pipes, and would otherwise choke them; but the best way of protecting the toe of the slope is to build a stout rubble wall, as suggested above in method No. 1. Without some such protection the slopes are in continual danger for long after they are made; they may stand the first winter, and even the second, without giving the least sign of a slip, and yet slip for nearly their whole length at the third winter, and give great annoyance. This, no doubt, is often due to the effect of weathering on the clay; but from whatever cause it arises, it at least shows that the work which is sufficient for temporary stability, does not always suffice for the permanent security of the cutting.

Experiments on Plate Heating by Liquid Fuel against Coal, made at Chatham Dockyard, May 26, 1869:

	Number of experiments.	Dimensions of furnace.	No. of grates.	Grate surface.	Description of plate.	Dimensions of plate.	State of furnace when put in.	Time of lighting or putting in plates.	Time of drawing plate.	Time employed in heating plate. h. min.	Combustible used.	Quantity of ditto.	State of plate when taken out.
Oil furnaces.	1	2.70 ft. × 5.0 ft. × 2.0 ft. high.	None	7 holes $\frac{1}{8}$ in. diam.	Armor.	7.3 ft. × 3.6 ft. × 6 in.	Cold furnace and cold plate	a. m. 8 30	a. m. 10 30	2 0	Creosote oil.	In heating the three plates, Nos. 1, 2 and 3, 67 gals., weighing 705 pounds were used.*	White hot; considered more than sufficient for bending; very equally heated.
	2	The same.	"	"	Armor.	9.4$\frac{1}{2}$ ft. × 3 ft. 3 in. × 6 in.	Hot from the preceding trial	10 55	p. m. 12 5	1 10	"		White hot; considered a very good bending heat.
	3	The same.	"	"	Keel plate	10 ft. 10 in. × 3.0 ft. × 1$\frac{1}{8}$ in.	"	p. m. 2 0	2 16	16	"		Very white; flattened when laid down by its own weight.
Coal furnaces.	4	21.0 ft. × 5.0 ft. × 2.6 ft. high.	2	16 ft.	Armor.	Same as in experiment No. 1	Cold furnace and cold plate	a. m. 9 0	12 50	4 50	Hartley main coal.	19 cwt.	About two-thirds of this plate were at an amealing heat; the part next the grate only was sufficiently hot for bending.
	5	The same.	2	"	Keel plate	Same as in experiment No. 3	Hot from the preceding trial	p. m. 1 50	2 51	1 0	"	3 cwt.	Two-thirds of the plate were nearly white hot, while the other part could not be flattened by hammering.
	6	17.0 ft. × 5.0 ft. × 2 ft. high.	3	19 ft.	Armor.	Same as in experiments Nos. 1 and 3.	Cold furnace and cold plate	a. m. 8 30	1 5	4 35	"	19 cwt.	Better heated than in experiment 4, but still unevenly heated, and for the greater part not sufficiently hot for bending.
	7	The same.	3	"	Armor.	Same as in experiment No. 4	Hot from the preceding trial	p. m. 1 25	4 15	2 50	"	12 cwt.	Altogether insufficient; an annealing heat only, and that very unequal.

* One cwt. coal was employed in heating generator from which the creosote vapor was supplied.

NEW BRIDGE OVER THE THAMES.

From a paper before the Civil and Mechanical Engineers' Society "On the bridge over the Thames carrying the West London Extension Railway." By Mr. LAWFORD, M. Inst. C. E.

This bridge consists of five segemental arches of wrought iron, each arch having a span of 144 ft. on the skew, with a rise of 16 ft. or 1-9th of the span. There are also, on the Middlesex side of the river, six, and on the Surrey side four, land arches of brickwork, each with a span of 40 ft. and a rise of 10 ft. The total length, therefore, of the structure is 1,270 ft. The abutments and piers of the five main openings are massive pieces of masonry, and are carried to a depth of 36 ft. below Trinity highwater mark, and 14 ft. below the bed of the deepest part of the river. The soffit of the arches at the crown is 22 ft. above Trinity high-water mark, in accordance with the requirements of the Admiralty. The level of the rails is 26 ft. above Trinity high-water mark. The width of the river between the two abutments is 776 ft. on the skew and 706 ft. on the square. The width of waterway afforded is 720 ft. The angle at which the bridge crosses the river is 75 deg. The greatest depth of water is 22 ft. below high-water, the average rise and fall of the tides at this place being about 13 ft. 6 in.

The piers were constructed in coffer dams, the inner row of piles being 5 ft. from the outer edge of the lowest course of masonry, and were driven to a depth of 15 ft. below the bed of the river; the outer row were 5 ft. from the inner row, and were driven to a depth of only 8 ft. from the same point, the space between the two rows of piles being filled with puddled clay. At the conclusion of the work the outer row of piles were drawn, but the inner row of piles were cut off level with the bed of the river. As the masonry of the piers proceeded, the space between them and the piles was filled with puddled clay, well trodden in to a height of 3 ft. above the bed of the river. Each pier stands on a bed of concrete 2 ft. thick, extending 3 ft. beyond the lowest course of footings. On the concrete is laid a course of York landings, 1 ft. thick, and projecting 1 ft. beyond the footings.

The foundations are carried up in a brickwork to within 2 ft. of the bed of the river, where there is a through course of stone 2 ft. thick. From this point to the springing of the arch the pier is faced with picked face ashlar of Bramley Fall stone. There is a second through course of stone half way between the bed of the river and the springing, and the upper, or last 7 ft. of the piers, including the springers, which are 3 ft. thick, are entirely solid stonework. The two abutments are built similarly to the piers, except that they have hollow chambers, filled with gravel to a height of 3 ft. above the springing of the arch; each abutment being just on the edge of the river required only half a coffer-dam for its construction. All stonework of both piers and abutments above springing height is tool dressed. The concrete used in this bridge was composed of five parts of gravel to one of blue lias lime, and the mortar of two measures of sharp sand to one of the same sort of lime.

Each of the river arches is composed of six wrought-iron ribs, arranged in pairs, 2 ft. 6 in. apart from center to center. The arch or voussoir of the four main or inside girders is formed of $\frac{3}{8}$-in. vertical plates, 39 in. deep at the springing and 24 in. deep at the crown, with double angle irons, each 4 in. by $3\frac{1}{2}$-in. by $\frac{1}{2}$ in., top and bottom, to which the flanges are attached by means of rivets. There is also a packing strip 8 in. by $\frac{1}{2}$ in. between the angle iron and the flanges. The flanges consist of two $\frac{5}{8}$ in. plates, 18 in. wide. The upper member of the inside ribs is a horizontal parallel girder, similarly constructed, but only 24 in. deep, throughout its entire length. The vertical web is $\frac{1}{4}$ in. plate from the pier to the point where the upper and lower member intersect, *i. e.*, 15 ft. from the center of the arch, and from this point both vertical webs are $\frac{3}{8}$ in. in thickness. The bottom flange of the horizontal girder consists of one plate $16\frac{1}{2}$ in. wide by $\frac{1}{2}$ in., two angle irons $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{2}$ in., and a packing strip 8 in. by $\frac{1}{2}$ in. The upper flange is 15 in. wide, all other dimensions being the same as those of the lower flange; but the top plate is slightly curved inwards towards the rails. In the two outside ribs the voussoir is constructed as already described, but is 30 in. deep at the crown and 39 in. at the springing. It may be as well to mention here that in these two girders, on the outside faces of the arch, all the rivets, excepting those in the angle irons, are countersunk, no cover plate either being visible at the joints. The whole centre web presents, therefore, the appearance of one smooth unbroken plate. This center web is $\frac{3}{8}$ in. plate, the two flanges are single $\frac{1}{2}$ in. plates 16 in. wide, the angle irons $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{2}$ in., and the packing pieces 8 in. by $\frac{1}{2}$ in. The upper member is constructed in the same manner as that of the inside rib, but it has throughout the whole span $\frac{1}{4}$ in. vertical plates, and is only 18 in. deep at the crown of the arch. The upper flange is 18 in. wide, and is parallel with the lower flange, which is only 15 in. wide. The angle irons and packing pieces are of the same dimensions as those already described for the inside top members. The total depth of the girders, both inside and outside at the center of the arch, is the same, viz., 48 in.

The sectional area of each of the four main girders is as follows:—In the arch at the springing, 80 square inches; in the upper member do., 43 square inches—total, 123 square inches; and at the center of the arch, where the upper and lower members are together, 105 square inches, the mean average being 114 square inches. These are the full sectional areas, including the rivets. The voussoir and the upper horizontal girder of the four main girders are connected together by a lattice spandrel, composed of H-iron, of three different sizes, viz., 7 in., 6 in., and 5 in. by $\frac{1}{2}$ in. A stiffening bar of flat iron, $\frac{3}{8}$ in. thick, is added to each side of the H-iron, connecting the lattice bars throughout at the angles of intersection. In the outside girders the lattice and stiffening bars are all made of double T-iron, riveted together, thus $\frac{\perp}{\mathrm{T}}$, and of the same dimensions as the H-iron. *i. e.*, 7 in. by $3\frac{1}{2}$ in., 6 in. by 3 in., and 5 in. by $2\frac{1}{2}$ in., all $\frac{1}{2}$ in. iron. Each pair of ribs is connected near the haunches by means of frames, composed of angle irons, cross-braced and riveted to the ribs, forming an open box girder. This principle is continued to the crown of the arch, where the voussoir and top girder unite in a double cell. Each pair of main girders are braced together at the haunches by means of trellis transverse girders 2 ft. 6 in. deep, carried up at equi-distant intervals to within 10 ft. of the center of the arch. There are seven of these in each half arch; they are composed of angle and bar iron, $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{2}$ in. The top members of the main ribs are secured together by the cross girders, which carry the roadway; the are fixed over the whole length of the bridge, 4 ft. apart from center to center, and are composed of a middle web of iron, 10 in. deep and $\frac{1}{2}$ in. thick, the bottom of which is flanged with double angle iron, $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{2}$ in., and the top by double channel iron, on the lower flange of which the buckle plate flooring rests. The cross girders rest on the lower flange of top main girder, and are secured in their places by iron knee-pieces, riveted through the center webs. The main or bearing girders are again cross-braced by diagonal rods, bolted to a center plate, and to brackets riveted on to each of the angles. There are three sets of these tie-rods in each half arch.

Upon the end of each arch or voussoir a plate of cast iron, 3 in. thick, is fixed, the back of which is planed quite true and even. These, again, fit into heavy cast-iron shoes (weighing 2 tons each), let into the stone skewbacks of the piers and abutments, and by means of wrought-iron wedges are finally adjusted in their seats. Contraction and expansion are provided for as follows:—Cast-iron standards are bolted to the stone-work of the piers and united by a cast-iron frame, secured with bolts and nuts. These standards have recesses to receive the ends of the horizontal girders, and secure them in position, at the same time allow for horizontal motion. A bed and bearing plate, planed perfectly parallel, are fixed under the ends of the horizontal girders, upon which they slide.

The railway is a double line of mixed gauge, and is carried over the bridge by means of longitudinal timbers with transons every 10 ft. Ash ballast is used all over the bridge. A cast-iron moulding is attached to the horizontal girder, throughout its whole length, and a cast-iron plinth is bolted on to the top of the same; an ornamental cast-iron parapet is fixed on the plinth, and the whole is surrounded by a wooden hand rail. In the experiments made for testing the quality of the iron, it bore a tensile strain of nearly 18 tons per square inch, without showing any signs of fracture.

The width of the bridge between the cast-iron parapets is 30 ft. in the clear. The total width of the piers from out to out above springing level is 35 ft. 6 in., and at that level, including the cut waters, 53 ft. 6 in. The total cost of the bridge was £104,000, or £82 per lineal foot, and £2 10s. per superficial foot. The materials used in its construction were 2,000 cubic yards of concrete, 11,100 cubic yards of brickwork in mortar, 130,000 cubic feet of stone, 2,160 tons of wrought iron, 366 tons of cast iron, 2 tons of lead, and 28,000 cubic feet of timber, exclusive of the piles. This bridge was the joint design of Messrs. Baker and Bertram, the chief engineers of the Great

Western and North-Western Railways. It was opened for public traffic on March 2, 1863, since which date some hundreds of trains have passed over it daily, and I am not aware that, up to the present time, any expense whatever—beyond the maintenance of the road—has been incurred, either in repairs or otherwise. The bridge was only 15 months under construction, *i. e.*, from the time the first stone was laid until a locomotive passed over the river. The bridge was very severely tested on January 7, 1863, by Captain Tyler. The narrow gauge load consisted of two locomotives and tenders, funnel to funnel, and two tank engines; total length of train 132 ft., total weight 176 tons. The broad gauge load consisted of two tank engines, in the same position as the narrow gauge engines, each drawing six loaded coal wagons; total length of train 276 ft., total load 292 tons; these two loads, collectively, being equal to about $2\frac{1}{3}$ tons per lineal foot. First, the narrow gauge load passed over No. 1 arch at speed, the deflection 5-100ths of a foot. Second, the broad gauge load passed at speed—same result. Third, the broad gauge load on one road and narrow gauge on the other, both passed together over No. 2 arch at speed. On going over No. 1 arch, No. 2 rose 3-100ths of a foot. On going over No. 2 it deflected nearly 10-100ths of a foot, rise and fall 13-100ths of a foot. Fourth, both loads were brought to rest on No. 2 arch, deflection 11-100ths of a foot. When the loads passed slowly over No. 3 arch, No. 2 rose 2-100ths of a foot, rise and fall 13-100ths of a foot. Both loads remained stationary for some time on this arch, but no further deflection took place, and, with the removal of the load, the girders rose simultaneously to their original height. Fifth, the same thing was done on No. 3 arch with a precisely similar result. Sixth, the same experiment was made on the fourth arch, and in exactly the same manner as the fourth experiment—rise of arch 2-100ths of a foot, deflection 10-100ths of a foot, rise and fall 12-100ths of a foot. Seventh, the same thing was done on the fifth arch; the rise was 2-100ths of a foot, deflection 8-100ths of a foot, rise and fall 10-100ths of a foot. The bridge was very steady throughout these experiments, and there was very little lateral vibration, even when both loads passed at the same time in the same direction, either slowly or at speed.

CEMENT FOR ROAD MAKING.

From the "Building News."

If there be one thing in ordinary life in which we seem to have made little improvement in late years, it is surely road making. Compared with the numberless improvements effected in all other directions, it may seem strange that we have learned so little wisdom in reference to this important public convenience. Our thoroughfares are, sewers and drains excepted, very much what they formerly were. The traffic has immensely increased; the wear and tear have proved proportionately great, while the difficulty of interfering with the traffic to execute repairs or renewals has grown more perplexing. Streets are constantly being pulled up, much to the inconvenience of the public, and most of all to shopkeepers; while newspaper complaints have become so customary that few persons heed them, and no one ventures to act upon them. We think the whole subject of road making deserves full and scientific inquiry, and he will be a public benefactor who can lead Englishmen* to improve their methods of laying down roads with greater facility, and of making them less perishable.

It is not because we think the use of Portland cement for road making will effect all we want that we direct attention to its employment for our public thoroughfares. By many it is at present regarded as little else than a novelty, and may, perhaps, be so considered for some time to come. A few years since Mr. Joseph Mitchell, until recently a general inspector of roads and bridges in the northern counties of Scotland, paid particular attention to the subject of macadamized roads. The cost of maintaining these roads, it is well known, is a considerable item in all local accounts. He made experiments which proved that a cubic yard of macadamized stone, when well pressed down in a box with a capacity of 27 cubic ft., contains 11 cubic ft. of vacuities; and that a roadway covered with 12 in. of metal, before it is consolidated into a smooth and useful surface, has a large portion of its stones crushed into small particles. He also discovered that more than one-third of its dimensions consisted of mud and sand. The result consequently has been that the stones in such a roadway, where the traffic is heavy and wet weather frequent, disintegrate to a very

* If the subject is unsettled in England, what is it in America?—Ed. *V. N. M.*

great extent; the greater the traffic, the greater the quantity of mud generated. Six or twelve months' traffic will play sad havoc in most of our public thoroughfares, as we all know; and not even the hardest stone can stand the heavy traffic of our great cities and towns. The ordinary mode of laying down streets accounts for much of this failure. We have before now denounced the loose methods which obtain throughout the country in reference to this matter. Nothing seems more absurd or primitive than to lay the granite in a bed of sand, beating it down a few inches, and then covering the interstices with sand that the first rainfall will speedily reduce to mud or wash away. And yet this is the ordinary process of constructing roadways, a process which necessarily leads to each stone being insulated, and, resting on a yielding surface, to give way very speedily. Mr. Mitchell found that in a street so constructed the ends of the causeway stones were worn down after twelve months' traffic from one-half to three-quarters of an inch. This, of course, arose from the fact of the percussion of the wheels of carts and carriages falling from the center of one stone on to the joint of the two adjoining, which sank from the pressure. "When a stone," he says, "has sunk bodily from one-half of an inch to an inch, or when a little hollow occurs in the pavement of the street, it will commonly be found that the adjoining stones are much worn, the hollow on the surface increasing the force and effect of the percussion of the wheels. The greater the hollow the greater is the tear and wear from the strokes of the wheels."

It was these and other facts which led Mr. Mitchell to consider the propriety of using Portland cement for roadways. Mr. Mitchell's plan is exceedingly simple, and its simplicity commends it to all minds. He first lays down a bed of cement concrete three inches deep, instead of providing a yielding surface. In cases where gravel is more easily procured and is cheap, it may be used instead of macadamized stone. The concrete soon gets firm, and of course excludes all moisture from below. He then places the paving-stones on this base, and, when brought to a perfect form, the joints are filled with cement grout. The paving-stones are five inches deep and three inches wide, a width of three inches being found to give a better hold to the horses' feet than the ordinary widths of 4 or 4½ inches. He holds that when properly consolidated such a surface is perfectly immovable to traffic and impervious to moisture. If, he adds, the causeway be well made, no irregularities on the surface should occur; when they do exist, it is attributable to defective workmanship.

This plan has been tried in three places with varied results, in the first case, at Inverness, in 1865; and at the end of two years, having been subjected to a heavy goods traffic, the road was perfectly sound, requiring no repairs, and presenting a marked contrast to the macadamized roadway adjoining it. The second attempt, in London, is an admitted failure. In this case the traffic was much more severe and trying. Mr. Cowper, the then Chief Commissioner of Works, consented to the inventor laying down 100 yards of his new road on the Mall in St. James's Park, at the foot of the Green Park. The surface subsequently broke up under the heavy traffic, much to the surprise of the inventor. For some time he was puzzled, but at last he solved the mystery. It would appear that the roadway at each end of the experiment was macadamized at the time when the experiment was made, and inadvertently the contractor's workmen were allowed by the person in charge to pass their roller from end to end before the cement was properly consolidated. The consequence was that the crystalline structure of the cement being injured, the surface of the road was found to need repair through its yielding to the incessant traffic. It appears to have been repaired by a coating of two inches of macadamized stone, which was rapidly ground down on the hard concrete by the vehicles. Mr. Mitchell observes in his account of the failure of this experiment: "As the bottom was entire and consolidated, had a coating of two or three inches of concrete been laid down, with the required time to consolidate, it would have answered all the purposes contemplated, but the surveyor deemed it his duty to remove the concrete surface entirely, which was only done at great trouble by means of levers and iron crowbars."

Mr. Mitchell was, however, not to be beaten. All inventors must provide against failure in the early history of their improvements, and the lesson derived from the experiment made in the metropolis was, and will be, of use to him in the future. His third attempt was at Edinburgh, at St. George's bridge, and at the end of twelve months the roadway was reported to be sound and immovable, notwithstanding the heavy traffic which it is well know passes over this important thoroughfare. One little failure, however, occurred, through inexperience. Small hollows showed themselves at the end of the winter, at the joinings along the center of the roadway. These hollows were soon filled up, and the result has since been eminently satisfactory.

It has been objected to these pavements that they produce more noise than the ordinary roadways; but, while admitting this, it is urged that the noise from the vehicles, though greater, is different, being more of a ringing sound, as if the street were bound up with frost.

The question of cost is an important consideration. It would seem that the concrete road at Edinburgh cost 6s. 8d., and the paved road 17s. per square yard, in addition to 1s. 8d. per square yard for excavating and removing the old road, and watching. It must be remembered that the roadway was but small, and had the experiment been on a larger scale, the cost might have been considerably less. The cement being cheaper in London, the cost of concrete roads would be proportionately less. A firm of engineers in Edinburgh made experiments on Mr. Mitchell's roadway, by which they discovered that it enabled loads to be drawn at a much less cost in tractive power. Thus, we are told that, as the result of the superior evenness and solidity of the roadway, a wagon of two tons' weight ascending a gradient of 1 in 80 required a traction of 70 lbs., while on a common macadamized road, the same weight required a traction of 140 lbs. The difference of one-half is, of course, a wide one. Again, on a road with wheel tracks through new metal, 340 lbs. were required; and on a road newly covered with metal, 560 lbs., all the gradients being 1 in 80. This point of the conservation of power is an important one, and speaks favorably for the new road.

Undoubtedly almost everything depends, in the construction of these roads, upon the quality of the cement and the carefulness with which the work is superintended and done. The inventor holds that the Portland cement should be of the best quality, and tested to bear a tensile strain of 500 to 600 lbs. on a bar $1\frac{1}{2}$ in. square. The cement must be allowed time to harden; a month was found sufficient in Edinburgh. This adds to the difficulty of using the material in the metropolis, where the roads are required for use immediately they are laid. It has been suggested that cement blocks, properly tested, should be used, and this would obviate the difficulty we have pointed out. At any rate, we hope that Mr. Mitchell may yet be permitted to make another experiment in London, where we have reason to believe it would be as successful as in Edinburgh. Mr. Reid, C. E., has expressed his opinion that an engineer might, with duly prepared and tested cement blocks, re-lay the whole extent of London Bridge in fourteen days. Such an event may not be altogether impossible.

THE METRIC SYSTEM.

From a lecture by the Rev. JOSEPH A. GALBRAITH, F. T. C. D.

From the "Scientific Opinion."

The jurors of the International Exhibitions of 1851, 1855, 1862, and 1867, all agreed to recommend the general adoption of the metric system by civilized countries. The International Statistical Congress, held at Brussels, Paris, Vienna, London, Berlin, and Florence, reported in favor of its adoption. There is a permanent committee of the British Association, called the Metric Committee, whose object is to forward the adoption of this system, for the sake of the benefit it would confer upon scientific investigators, engineers, and students in the various arts and sciences.

The metric system is, at present, used throughout Europe and America by a population of 150,000,000 of people. Nearly 60 per cent of the total export and import trade of the United Kingdom is carried on with people using the metric system.

The fundamental principle of the metric system is that it should be international. This appears from the report of the Academy of Sciences, signed by its president, Cordorcet, and presented to the National Assembly in March, 1791, by M. Talleyrand. The report states that, after careful consideration of the question, the Academy had come to the conclusion, that every arbitrary consideration should be excluded from the proposed system; that it should not possess any feature which could raise even a suspicion of the particular interest or influence of France. In a word, the Academy desired so to frame the system, that if its principles and details alone, apart from its history, should descend to posterity, it would be impossible to divine by what nation it was designed or executed.

COUNTRIES IN WHICH THE METRIC SYSTEM HAS BEEN WHOLLY ADOPTED.

	Population.
France, with Algiers	40,500,000
Belgium	5,000,000
Netherlands and Colonies	23,000,000
Italy	24,000,000
Papal States	700,000
Spain and Colonies	21,000,000
Portugal and Colonies	8,000,000
Greece	1,200,000
Mexico	8,000,000
Chili	1,600,000
Brazil	8,000,000
New Grenada	2,000,000
Other South America Republics	3,000,000
	146 000.000

COUNTRIES IN WHICH THE METRIC SYSTEM HAS BEEN PARTLY ADOPTED.

	Population.
Switzerland	2,500,000
Hanse Towns	500,000
Denmark	3,000,000
Austria	37,000,000
	43,000,000

COUNTRIES WHERE IT IS PERMISSIVE.

	Population.
United Kingdom	29,000,000
United States of America	31,000,000
Prussia and North Germany	30,000,000
	90,000,000

Principles and Nomenclature of the Metric System.—1. It is international. Its framers intended it to be so, and so well carried out their principle, that nearly 200,000,000 people have already adopted it.

2. Its principal units are derived from natural standards; the dimensions of the earth, and the weight of water.

3. It is rational, because all its parts, proceeding regularly from the unit of length, are connected together by rational relations.

4. It is decimal, that is to say, all its parts are multiples or submultiples of the number ten on which our arithmetic is founded.

5. The nomenclature is simple, expressive, and well adapted for international use. It consists of only eleven words. The name of each weight or measure tells its own story, and as all the words are derived from the Greek and Latin languages, in which all civilized countries have an equal interest, no national sentiment is interfered with.

Unit of Length.—To establish the unit of length, the Commission appointed by the French Government proceeded to calculate the length of a quadrant of the earth, from the measured length of an arc of the meridian, the extremities of which were Barcelona and Dunkirk, stations which are nearly north and south, and comprise about 10° of latitude, situated very nearly equally on each side of the mean latitude 45° north. The linear standard used in this survey was the toise of Peru, so called from its having been used by Lacondamine, in the year 1756, in the measurement of the Peruvian arc. This toise or fathom was divided into 6 ft., the foot into 12 in., and the inch into 12 lines. The calculation founded on the measurement of the Barcelona-Dunkirk arc gave as the length of the quadrant of the meridian 5,130,740.75 toises, from which the number of lines may be calculated as follows:

5,130,740.75	Toises.*
6	
30,784,444.20	Feet.*
12	
369,413,330.40	Inches.
12	
4,432,959,964.80	Lines.

The ten-millionth part of this was selected as the meter or unit of length. Therefore

Meter = 443.296 Lines.

Unit of Land Measure.—The unit of land measure is the are, and is equal to a square having for its side a line of ten meters.

Unit of Capacity or of Liquid and Dry Measure.—The unity of capacity is the liter, and is equal to a cube having for its side one-tenth of a meter.

Unit of Weight.—The unit of weight is the gram, and is the weight of a cube of cold water having for its side one-hundredth part of a meter.

Multiples and Submultiples.—The multiples of these units are expressed by prefixes taken from the Greek language, and are as follows:

Deca,	signifying	Ten times.
Hecto,	"	Hundred times.
Kilo,	"	Thousand times.
Myria,	"	Ten thousand times.

The submultiples are expressed by prefixes taken from the Latin language, and are as follows:

Deci,	signifying	Tenth part.
Centi,	"	Hundredth part.
Milli,	"	Thousandth part.

* There is surely some mistake here.—Ed.

SYNOPTIC TABLE OF THE METRIC SYSTEM.

Units.

METER—ARE—LITER—GRAM.

10,000 times, Myria. 1,000 " Kilo. 100 " Hecto. 10 " Deca.		
	Unit.	
		Deci, 10th part. Centi, 100th " Milli, 1,000th "

Formation of Tables.—The tables of length, land measure, capacity and weight, are readily formed by placing the respective units in the place of unit in the synoptic table:

Length.	Land measure.	Capacity.	Weight.
Myriameter			
Kilometer			Kilogram
Hectometer	Hectar	Hectoliter	Hectogram
Decameter		Decaliter	Decagram
METER.	ARE.	LITER.	GRAM.
Decimeter		Deciliter	Decigram
Centimeter	Centiar	Centiliter	Centigram
Millimeter		Milliliter	Milligram

It may be observed that some of these tables are more extensive than others; according to the nomenclature they should be equal term for term, but practice has determined the limits, as given above.

Relation of Weight and Linear Measure.—According to the metric system, the unit of weight, or the gram, is the weight of a cubic centimeter of water; therefore, one thousand of these, or one kilogram, is the weight of a liter or cubic decimeter of water; one thousand kilograms is the weight of a cubic meter of water. This weight is called a millier, or metric ton.

Metric Units expressed in English Measure.—The following table of values is the result of exceedingly accurate measurements and calculations:

Meter = 39.370790 inches.
Are = 119.60333 square yards.
Liter = 61.02705 cubic inches.
Gram = 15,432.348 grains troy.

Approximate Equivalents.—The following table of approximate equivalents answers very well for calculations in which extreme accuracy is not required:

LENGTH.

64 meters = 70 yards.
25.4 millimeters = 1 inch.

LAND MEASURE.

1 are = 4 perches.
10 ares = 1 rood.
1 hectar = $2\frac{1}{2}$ acres.

LIQUID AND DRY MEASURE.

$4\frac{1}{2}$ liters = 1 gallon.
1 hectoliter = 22 gallons.

WEIGHT.

1 kilogram = 22 lb. av.
30 grams = 17 drams av.

LINEAR SQUARE AND CUBIC MEASURE.

10 meters = 11 yards.
10 sq. meters = 12 sq. yards.
10 cub. meters = 13 cub. yards.

How to make a Meter.—Measure off on a slip of wood 3 ft. 3 in. and 3 eighths, divide this length into ten equal parts for decimeters, into 100 equal parts for centimeters, and into 1,000 equal parts for millimeters.

This meter is larger than the standard meter by only one part in ten thousand, and may, therefore, be considered as practically accurate.

How to make a Liter.—Take a piece of card-board, and on it construct a square whose side shall be 3 decimeters; subdivide this into 9 square decimeters, cut away the corner squares, and bend up those which remain into a cubical vessel.

How to make a Kilogram.—Balance a liter on a pair of scales with an exact counterpoise; fill the liter with cold water, the additional weight which will be required to restore the balance will be a kilogram. One-thousandth part of this will be a gram.

Retention of the Pound Weight.—In countries which use the metric system, the pound is just as familiar as with ourselves. The half kilogram, or weight of 500 grams, is universally called the pound, and is used in retail transactions. If this weight be called, as it is in Prussia, the new pound, we shall have

10 new pounds = 11 lb. av.

Prices by the pound should, therefore, be increased by 10 per cent if we adopted the metric system. Since 10 meters = 11 yards, the same observation may be made as to prices by the yard.

Consequent Disturbance of Trade.—The prices of nearly every commodity are quoted by the

Hundredweight = 112 lb.
Ton = 2,240 lb.

These weights are only $\frac{1}{64}$th part less than the corresponding weight used in Continental business—namely,

Centner = 50 kilograms = $110\frac{1}{4}$ lb.
Ton = 1,000 kilograms = 2,205 lb.

The consequent change in quotations would amount only to $3\frac{3}{4}$d. in the £1; a change so trifling would cause little or no disturbance in daily business.

THE FORMS OF STEAMSHIPS.

From "Engineering."

At the time when the principal resistance to the motion of vessels through water was believed to be head resistance, or so-called midship section resistance—and the time is not so long ago—nearly all attempts at improvement in form consisted in fining the bow and stern; in diminishing the area of midship section, or rather in providing a given displacement by means of longer, narrower, and shallower ships; and, finally, by introducing Mr. Scott Russell's elegant refinement of wave lines. It was very long ago evident, however, that there was another resistance, viz: that occasioned by the adhesion of the water to the entire wetted surface of the vessel—a resistance now widely and well known as "skin friction." All resistance that was not head and stern resistance was undeniably skin friction, since there were no other known or conceivable resistances to be overcome. But while vessels were propelled by sails only, it was impossible to ascertain the real amount of power expended in driving them, and thus there were no means of ascertaining the relative proportions of the two kinds of resistance to each other.

It was possible, even then, however, to calculate nearly the amount of head resistance for a vessel of given midship section and given angle of bows at any given speed. A flat-fronted or square-ended bow, moving at any given velocity, would, it is true, carry before it a wedge of what may be called dead water, and although the identical water thus carried might be, from time to time, changed by internal currents, generated by fluid friction, this bow of dead water would divide and turn aside the water in front. The case is the same as that to be noticed on the up-stream side of bridge piers, where floating objects are seen to diverge from the general direction of the current, preparatory to their taking one or the other side of the pier, one hundred or even two hundred feet above the pier itself, according to the thickness of the pier and the rapidity of the current. But this does not alter the fact that all the particles of water in front of the bow, supposing them to be at rest, would, if fairly struck, without the diversion caused by the liquid bow of "dead water," be turned aside, at right angles, and with the same velocity as that of the vessel itself. Thus, if the velocity of the vessel were $17\frac{1}{3}$ ft. per second, corresponding to about $10\frac{1}{4}$ knots an hour, the water would be turned aside with the same velocity of $17\frac{1}{3}$ ft. per second, corresponding to a head of 4.6 ft., and this would occasion a head resistance of 2 lbs. per square inch over the whole midship section of the vessel. If the midship section of a sailing vessel of, say, 36 ft. beam and 18 ft. draught were 500 sq. ft., or 72,000 sq. in., the head resistance would be 144,000 lbs., and at the given speed of $17\frac{1}{3}$ ft. per second, or 1,040 ft. per minute, about 4,540 horse power would be required to overcome the head resistance alone. Supposing, also, that the stern were cut square across, the water falling in behind it would, on striking, be as much below the general level of the sea, and thus there would be a corresponding minus resistance, representing an additional 4,540 horse power, making 9,080 horse power requisite for propulsion, apart from skin friction along the bottom and sides.

This would appear an astonishing measure of resistance at so moderate a speed as $10\frac{1}{4}$ knots, and for a ship of such moderate midships section, but it is, we believe, correct. As soon, however, as we alter the bows and stern to a wedge form, the head and stern resistances diminish rapidly, in fact in proportion to the square of the sine of the angles to which the bow and stern are beveled. If these formed an angle of but 30° on each side of the keel, the bow and stern thus forming, each, an equilateral triangle, the head and stern resistance would be diminished to one-fourth of what has been estimated for a flat-ended bow and stern, supposed to strike and receive the water at right angles to their faces. If the bow and stern were, each, made twice as long as their width, giving an angle of 1 in 4, or 14° 30′, on either side of the keel, the water would be turned aside and afterwards replaced with but one-fourth the velocity estimated in the case of the square-ended bow and stern, and the power thus required would be but one-sixteenth that first estimated, the power required being always as the square of the velocity of lateral displacement. If the bow and stern were again beveled to an angle of 1 in 6 or 9° 30′, on either side of the keel, the length of bow and stern, respectively, being three times the breadth of beam, the head and stern resistance would be but the one-thirty-sixth part that first estimated; and if an angle of 1 in 8, or 7° 10′, were adopted, the head and stern resistance would fall off to but one-sixty-fourth that estimated for the square-ended bow and stern. It is thus that the head and stern resistances fall so rapidly, as the bows and stern are made finer and finer, and that they soon cease, as Mr. Phipps has shown in his letters, to form the principal resistance. But the resistance implied by a wedge formed bow and stern is a resistance involving the loss of dismissing the water, displaced laterally, with a final velocity sufficient to carry it beyond the mid-body of the hull, whereas it should fall to rest alongside. Every inch of motion of the displaced particles which carries them beyond the ship's beam is a direct loss of power. The fore body, therefore, is eased off by a curve connecting it with the mid-body to diminish the displacing motion, or, rather, to allow the displaced particles to drop of themselves into their proper places by expended momentum. Finally, by hollow water lines at the entrance, the shock, whatever it may be, of instantaneously giving to the displaced water its full lateral velocity is greatly lessened and nearly extinguished, by setting it gradually into a motion like that of a pendulum.

Following the same general principles in forming the stern, we reach a point where the head and stern resistances may be diminished, in some cases, to the one-hundredth part of those attending a flat-fronted bow and a flat-backed stern.

Simple and obvious as this general view of the resistances to the motion of vessels through water may appear, the subject is one which has very seldom, if ever, we think, been popularly treated, and it is one upon which misconceptions may be easily formed from the many apparent difficulties with which a first view surrounds it. If not a spontaneous, it is, at least, a not unwilling acknowledgement to say that some of these misconceptions have been embodied, before now, in our own columns, and Mr. Phipps, who has so well considered the phenomena of the hydraulics of marine propulsion has done good service in suggesting, in his own courteous manner, what was to have been said to the contrary.

If, then, as can be estimated with tolerable exactness, we know the effective engine power actually utilized in driving a steamship, or, in other words, its absolute resistance; and if we then find by calculation that the head and stern resistances form but a small fraction of this resistance, the remainder can be nothing else than skin friction, since, as already observed at the commencement of this article, there are no other known or conceivable resistances beyond those, of course, of wind, tide, and currents, to be overcome. It must be acknowledged that we have long ago passed that stage of improvement in the forms of vessels which left their resistance of form a minimum and their resistance of surface a maximum.

The New Wonders of the World.—Under the heading, "Mirabilia Mundi: VIII, IX et X," "Engineering" says: The Suez Canal, which, not a dozen years ago, was ridiculed here, in engineering England, as a visionary, if not an impractical, scheme, will be virtually completed this year, and Captain Tyler is already reporting to the Board of Trade upon the probable early passage of large ocean steamships direct from Port Saïd to Suez, on their way from Southampton to Bombay. After passing through the impossible stage, and landing safely on the improbable, this great work was said to be one of £. s. d., as, indeed, most works are, and money, it was said, could not be found to make it. But it will not have cost, according to authoritative statement more than £10,000,000 when completed, a cost not so very far beyond that estimated for the Metropolitan Railway system with its extensions.

The Pacific Railroad, completing the chain of railways 3,300 miles long, from New York to San Francisco, or, in other words, connecting the Atlantic and Pacific oceans, has already been opened this year, although in an incomplete state. But it is something that passenger trains are running daily over 1,721 miles of a continuous new line, made wholly within the last three years, and crossing a mountain range at an elevation higher than that of any other railway in Christendom.

The Mount Cenis Tunnel, as long, 7½

miles, as that part of the Thames, following all the windings, between London Bridge and Putney Bridge, is making rapid progress, and may already count as one of the wonders of the world. Yet even now, when so far advanced towards completion, the great tunnel affords room for the most doubtful speculation, the "Times" Paris correspondent dwelling gloomily upon the prospect of tapping a lake somewhere inside of the mountain!

Wonders never cease, yet the French Atlantic Cable, if successfully laid this year, as presumably it will be, will be no wonder at all, for are there not two cables like it already laid across the bed of the Atlantic?

We now perceive that no one of these great works possessed the fatal defect of impossibility; indeed, they almost appear as if, from the first, they were conspicuously practicable and simple in their character, requiring, of course, time and money, and, perhaps, just a *little* skill. None of them happen to be the works of English engineers, so we can afford to be somewhat complaisant — don't let us say patronizing.

But there is a work in prospect which English genius may yet achieve — and it will assuredly be by English genius if achieved at all—which, not in mere length, nor in geometrical magnitude, but in the stretch which it might impose upon the highest resources of the combined skill, patience, and courage which a whole institute of engineers ever possessed, will surpass any one of the great modern wonders of the world which we have enumerated. That work is the Channel Tunnel. It is a work depending upon a great engineering IF, and a great financial IF, and possibly, although we trust not, upon a great political IF. Of the three *ifs*, possibly the engineering *if* is the greatest, although we would wish to believe otherwise — indeed, there *are* reasons for believing otherwise. In that submarine valley between Dover and Cape Grisnez, twenty miles across, and 200 ft. deep, can the chalk be depended upon as continuous? Mr. Hawkshaw's borings have probably already well-nigh settled that. A single deep fissure, filled with sand, would pour in a torrent, under a pressure, in mid-channel, of at least 100 lbs. per square inch, sweeping everything beneath it. One is tempted into a wide field of geological speculation upon the subject, but it may be dismissed for the present with this hasty suggestion.

IRON SHIPBUILDING.

Abstract of a paper before the London Association of Foremen Engineers, by Mr. James Rae, and of the discussion, by Mr. E. J. Reed.

The frequent disasters to iron ships must be in most cases attributed to defective construction. Iron ships, as a rule, were built with frames of that metal, the outer skin being formed of plates of iron and the inner one of timber planking. This latter served as a floor for the reception of the cargo, but it was no safeguard in the event of the outer skin being penetrated. Great stress had sometimes been put upon the efficiency of bulkheads. Practically they were really of little value. Steamships were usually furnished with four or five. These were supposed to be water-tight. Too frequently it was found, in the fell moment of peril, that they were nothing of the kind, and that after a collision it might be said of the vessel that she contained "water, water everywhere," whilst the pumps were incapable of discharging it. Bulkheads were, in ninety-nine cases out of the hundred, illusory and deceptive protectors of iron ships. Vessels of this kind, as now constructed, were calculated well enough for ordinary service under favorable circumstances, but were totally unfitted to contend against the extraordinary accidents which often befell them at sea. It was quite true that the past twelve years had witnessed great improvements in the construction of iron vessels, both as regarded the quality of the material used and in its mode of application. The author of the paper introduced at this point some startling facts which had come under his own notice when engaged as manager for a large shipbuilding company, and which demonstrated very forcibly the haphazard modes of construction commonly practiced not many years since. Mr. Rae also took some credit to himself for remedying the evils to which he referred, and especially considered himself entitled to commendation for having been the first to introduce the plate-planing machine into the shipbuilding yard. This apparatus was now almost universally employed instead of, or as supplementary to, the shearing machine, and Lloyd's rules distinctly specify that all "butts" shall be planed. The economy and the excellence of iron shipbuilding had been enhanced in a remarkable degree by the use of the planing machine.

The author next addressed himself to the question of internal defects in the construction of iron ships, and pointed out more particularly the weakness which was formerly observable in regard to the head and stern. In 1858 he decided to commence an improved system of connecting the stem and stern of vessels entrusted to his building with the keelson. The keelson plate was, in reality, carried up the stem and stern to a considerable height, and the solidity of the vessel was thus increased three-fold. The plan was patented, but, by a legal quibble, the inventor derived no advantage in a pecuniary sense, but, on the contrary, sustained a heavy loss in the shape of costs. The Admiralty had adopted the scheme without recognizing its promoter, and it was now public property, for all who were engaged in iron shipbuilding know its value and used it as freely as the Government.

Mr. Rae then proceeded to say that all iron vessels ought to be built with an internal as well as an external iron skin, the latter of course being of the greater thickness. Both skins should be made perfectly watertight. Between the inner and the outer skins a series of bulkheads, say 9 ft. apart, and extending from gunwale to gunwale, should be affixed. The spaces between the bulkheads should be filled in with asphalte, so as to prevent water passing from one space to another. Such an arrangement would add but little to the original cost of the ship, whilst it would increase her strength fully fifty per cent.

Mr. E. J. Reed, Chief Constructor of the Navy, commenced the discussion which followed the paper, and in doing so said that he agreed with its author as to the generally faulty construction of iron ships as built some few years since. Even now he thought that legislation might be beneficially employed in regard to the construction of iron ships for commercial purposes. He considered that the Admiralty had not acted unfairly towards the reader of the paper. That gentleman had no doubt discovered the weak points to which he had referred in regard to the stems and sterns of the older iron ships, but so had many others, and it was hardly to be expected that so self-evident an improvement could come under the prohibitory provisions of letters-patent.

As to the double-skinned vessel with asphalte "filling" between the bulkheads, he had little faith in it. The ship in such case would be permanently loaded very much to her detriment, whilst the contingent advantage was problematical. He wished also to say that in every instance where bulkheads were used in the royal navy, their water-tight qualities were tested by hydraulic pressure.

EXPLOSIVE AGENTS.

Abstract of a paper read before the Royal Society by F. A. Abel, F. R. S.

The degree of rapidity with which an explosive substance undergoes metamorphosis, as also the nature and results of such change, are, in the greater number of instances, susceptible of several modifications by variation of the circumstances under which the conditions essential to chemical change are fulfilled.

Excellent illustrations of the modes by which such modifications may be brought about are furnished by gun-cotton, which may be made to burn very slowly, almost without flame, to inflame with great rapidity but without development of great explosive force, or to exercise a violent destructive action, according as the mode of applying heat, the circumstances attending such application of heat, and the mechanical condition of the explosive agent, are modified.* The character of explosion and the mechanical force developed, within given periods, by the metamorphosis of explosive mixtures, such as gunpowder, is similarly subject to modifications; and even the most violent explosive compounds known (the mercuric and silver fulminates, and the chloride and iodide of nitrogen) behave in very different ways under the operation of heat or other disturbing influences, according to the circumstances which attend the metamorphosis of the explosive agent (*e. g.*, the position of the source of heat with reference to the mass of the substance to be exploded, or the extent of initial resistance opposed to the escape of the products of explosion).

Some new and striking illustrations have been obtained of the susceptibility to modification in explosive action possessed by these substances.

The product of the action of nitric acid upon glycerine, known as nitroglycerine or glonoine, which bears some resemblance to chloride of nitrogen in its power of sudden explosion, requires the fulfillment of special conditions for the development of its explosive force. Its explosion by the simple ap-

---

* Proceedings of the Royal Society, vol. xiii., pp. 205 *et seq.*

plication of heat can only be accomplished if the source of heat be applied, for a protracted period, in such a way that chemical decomposition is established in some portion of the mass, and is favored by the continued application of heat to that part. Under these circumstances the chemical change proceeds with very rapidly accelerating violence, and the sudden transformation into gaseous products of the heated portion eventually results, a transformation which is instantly communicated throughout the mass of nitroglycerine, so that confinement of the substance is not necessary to develop its full explosive force. This result can be obtained more expeditiously and with greater certainty by exposing the substance to the concussive action of a detonation produced by the ignition of a small quantity of fulminating powder, closely confined and placed in contact with, or proximity to, the nitroglycerine.

The development of the violent explosive action of nitroglycerine, freely exposed to air, through the agency of a detonation, was regarded until recently as a peculiarity of that substance; it is now demonstrated that gun-cotton and other explosive compounds and mixtures do not necessarily require confinement for the full development of their explosive force, but that this result is attainable (and very readily in some instances, especially in the case of gun-cotton) by means similar to those applied in the case of nitroglycerine.

The manner in which a detonation operates in determining the violent explosion of gun-cotton, nitroglycerine, etc., has been made the subject of careful investigation. It is demonstrated experimentally that the result cannot be ascribed to the direct operation of the heat developed by the chemical changes of the charge of detonating material used as the exploding agent. An experimental comparison of the mechanical force exerted by different explosive compounds, and by the same compound employed in different ways, has shown that the remarkable power possessed by the explosion of small quantities of certain bodies (the mercuric- and silver-fulminates) to accomplish the detonation of gun-cotton, while comparatively very large quantities of other highly explosive agents are incapable of producing that result, is generally accounted for satisfactorily by the difference in the amount of force suddenly brought to bear in the different instances upon some portion of the mass operated upon. Most generally, therefore, the degree of facility with which the detonation of a substance will develop similar change in a neighboring explosive substance, may be regarded as proportionate to the amount of force developed within the shortest period of time by that detonation, the latter being, in fact, analogous in its operation to that of a blow from a hammer, or of the impact of a projectile.

Several remarkable results of an exceptional character have been obtained, which indicate that the development of explosive force under the circumstances referred to is not always simple, ascribable to the sudden operation of mechanical force. These were especially observed in the course of a comparison of the conditions essential to the detonation of gun-cotton and of nitroglycerine by means of particular explosive agents (chloride of nitrogen, etc.), as well as in an examination into the effects produced upon each other by the detonation of those two substances.

The explanation offered of these exceptional results is to the effect that the vibrations attendant upon a particular explosion, if synchronous with those which would result from the explosion of a neighboring substance in a state of high chemical tension, will by their tendency to develop those vibrations, either determine the explosion of that substance, or at any rate greatly aid the disturbing effect of mechanical force suddenly applied, while, in the instance of another explosion, which develops vibratory impulses of different character, the mechanical force applied through its agency has to operate with little or no aid; greater force, or a more powerful detonation, being therefore required in the latter instance to accomplish the same result.

Instances of the apparently simultaneous explosion of numerous distinct and even somewhat widely separated masses of explosive substances (such as simultaneous explosions in several distinct buildings at powder-mills) do not unfrequently occur, in which the generation of a disruptive impulse by the first or initiative explosion, which is communicated with extreme rapidity to contiguous masses of the same nature, appears much more likely to be the operating cause, than that such simultaneous explosions should be brought about by the direct operation of heat and mechanical force.

A practical examination has been instituted into the influence which the explosion of gun-cotton, through the agency of a detonation, exercises upon the nature of its metamorphosis, upon the character and effects of its explosion, and upon the uses to which gun-cotton is susceptible of application.

THE VENTILATION AND TRAPPING OF DRAINS.

From a paper before the Society of Arts, by JAMES LOVEGROVE, Esq., Assoc. Inst. C. E.

The subject embraces the ventilation of drains, the trapping of gullies, and the various modes adopted for preventing sewer air passing out of gully and drain inlets.

The author of this paper has been led to attach considerable importance to the subject of drain ventilation, in consequence of having, in many instances, observed in houses where sanitary works had been carried out, a larger amount of effluvia after the execution of drainage works than existed before. He therefore purposes, in order that the subject may be fully and fairly put before the Society, to refer to the various means by which sewage matter has hitherto been conveyed from houses; to notice the effect upon the air in drains of discharging sewage matter into them; to suggest a new mode of ventilation; and also to consider the means usually employed to prevent the escape of sewer air through gully and drain inlets.

Some twenty or thirty years ago, public sewers were permitted to receive waste and refuse waters only, the closet drainage being carried into cesspools. The wash-house sink discharged the waste on to the surface of the back yard, by a pipe which passed through a hole in the external wall; the other waste water flowed along an uncovered drain beneath the floor of the house, and thence over the surface of the footway into the side channel of the street, so that, at all times during the day, a dirty stream of sewage might have been seen flowing along the channel. The exhalations from the uncovered cesspool, from the soaked and saturated materials of the uncovered drain, and from the exposed stream of sewage in the street, were most offensive. A covered sewer along such a street was next introduced. Gradually, covered drains were constructed beneath the houses, and connected with the new sewer, but with untrapped inlets, and untrapped gullies were also formed in the street channels to carry off the surface water. Thousands of cesspools were next connected with the sewer by overflow drains, and these allowed the effluvia therefrom to escape through the inlet opening, and caused a nuisance as great, or nearly so, as existed under the original state of things.

The next step was that of abolishing cesspools, and fixing pan-inlets, in direct connection with the drain leading into the sewer. The result was that, although the nuisance arising from the cesspools had been removed, the effluvium escaping through the untrapped drains and gullies was increased tenfold. The cesspool had been a long-standing abomination before the water-closet was thought of as the readiest way of getting rid of the nuisance. But this remedy, though so universally adopted, should be regarded by all as one of a palliative character only, as it not only causes the pollution of our rivers, but requires more than half the water supply to keep the closets clean. It is, however, hoped that modes of collecting the excreta and the most valuable portion of town sewage, without destroying their valuable properties, will, ere long, be introduced, and that the sewers will simply be put to their original use of receiving waste and refuse waters only. The dry earth closet may be a step in the right direction, and should receive a fair trial, in spite of the few difficulties which have to be met with at the outset.

In inquiring into the causes of air currents, either from or within drains, it is suggested that the variable flow of sewage has a powerful influence on the air within the drain, whilst that produced by rainfall has still greater, and the variations of tempera-

ture are another cause of displacement and renewal of drain air. The table shows a series of observations taken at the outlets of drains, at the points of connection with the sewer. They were taken by Biram's anenometer, and the results show that up and down currents of air are constantly passing to and fro. Whenever an up-current issues through a drain opening, it must be manifest that some of the inlets of such drains are untrapped, and, therefore, sewer air must be escaping through such untrapped inlets, to the danger of those who reside in the house. In the construction of gully inlets there are two principles which should be strictly observed, viz.:

1. To prevent, as far as practicable, the entry of road detritus into the sewer.

2. To prevent the escape of sewer air through the inlet.

Various methods have been adopted. Twenty different forms of traps in general use are all dependent on being constantly charged with water, and may be easily proved to be inefficient for the purposes for which they were designed, and for these reasons should be condemned. The sewer air is separated from the atmosphere by the ¼-inch of water, or at the most an inch, and a few days' dry weather is sufficient to untrap most of the gully inlets, as the water quickly evaporates to below the siphon-dip. This evaporation is aided, in many cases, by the absorbing power of the materials with which the inlets are constructed, and also by matters falling into them. These gully traps are often fixed in a narrow street close to the open doors and windows of the houses, and are, it is feared, in many instances, the cause of much ill-health. Traps constructed on this principle have been observed by the author in an untrapped condition, in Derby, Leicester, Windsor, and other places. Another form of trap, largely used for street gullies in the metropolis, is known as the shackle-flap, sometimes fixed at the end of a 12-inch or 15-inch length of pipe, and sometimes in the form of a square block. The flap and its seating form two plain metallic surfaces, and it therefore does not admit of partial separation of the surfaces, as the smallest possible opening made by the overflowing water separates the surface throughout, so that, while the water is flowing through the lower part of the valve, the sewer air escapes through the upper part. The flaps are sometimes fixed at the point of connection with the sewer; their action has been tested where thus fixed. A lighted candle has been held at the sides of the flap during the passage of water through the gully, and a strong current of sewer air was found passing through the upper part of the flap during the period of flow. The system adopted by the author is constructed on the two principles hereinbefore mentioned, and forms a combination of the siphon-dip and shackle-flap. It is made in two forms; one form having the appearance of a bent tube, nearly semicircular in shape, and inserted so that one end of the tube, called the siphon-dip, dips into the cesspit beneath the gully grating, and the other discharges into the outlet, the valve-flap being fixed within the tube. The other form is that of an oblong block of stoneware, having a 6-inch opening formed diagonally through it, so that the valve on the outlet side is from 1 to 2 inches higher than the opening in the block on the cesspit side, both on the same principle, but in different form. The siphon-dip prevents the escape of sewer air through the upper part of the shackle-flap during the period of flow, and the flap resists the upward pressure of the sewer air, thus effectually sealing the inlet. The pressure of the sewer air within assists in closing the flap, whilst the pressure on the inner face by the atmosphere opens the flap, and allows a refreshing current of air to pass into the sewer. This current is generally so strong as almost to blow out the light when placed near to the flap, and should be maintained, but so as not to admit of the escape of sewer air.*

The escape of sewer air into houses gave rise to the adoption of various forms of traps. For drain inlets, I believe the first trap used was the dip-trap—a brick cesspit formed usually about 18 in. square and 6 in. below the drain, the inlet on one side being separated from the outlet on the other side by a division of stone, slate, or iron, made to dip about an inch into the water of the drain. The well-known common siphon was an improvement on the old dip-trap for the main line of drain, and in a ventilated drain these are efficient, inasmuch as, from one source or another, they are always charged with water. This form of trap is used by the author in combination with an air tube and valve, the latter acting as a ventilator. The principle of the water-dip has been put into

* Gully and drain traps on this system are made by Mr. Jennings, of Lambeth.

various forms of drain inlets, but they all are dependent on a very small thickness of water for their action, and are quickly untrapped by evaporation, and then the result is precisely the same as if there were no trap at all. The common bell-trap is more frequently met with than any other form of trap. The mere film of water at the rim of the inverted bell is supposed to prevent sewer air passing through, but, generally speaking, when the sewers are in the most foul condition, that is, in the summer season, the required film of water is not in the trap, and it then forms a sewer ventilator. A piece of house-flannel, cotton, or other similar matter entering the bell-trap inlets, will often hang partly in the bell basin and partly out, and, by siphonic action, quickly draw off the water to a level below the rim of the inverted bell. These traps exist in almost every house, and are the cause of a large amount of illness. These remarks are applicable to all the forms of trap dependent on a constant film of water for their action, which are, consequently, not reliable.

[The paper then gives a number of examples of drains becoming untrapped in hospitals, residences, &c.; among others, the following:]

In a public hospital, near Portman-square, a brick drain in direct connection with the sewer passed sewer-air inwards so strongly as to blow out the flame of a candle. This drain continued through the building, and received in its way the raised sink-inlets, also the drainage from the lavatories, sinks, and water-closets on the upper floor. In this case, when water was passed from one or other of the inlets, it caused the contained air first to press against the water in the inlet water-traps, and, on reaction, to draw off sufficient water to untrap the inlet. Thus, through one or other of the inlets, air was generally escaping into the house.

In further considering the action of drain-traps, we will refer to a drain trapped at its outlet with a shackle-flap, and the several inlets trapped with the ordinary water-traps. When water is poured into a drain thus constructed, the result depends in a measure on the relative weight of the shackle-flap at the outlet as compared with the resisting power of the water-traps. If the flap be lighter, the pressure exerted on the air contained in the drain by the in-flowing water, will act on the inner face of the flap, force it open, and discharge a bulk of air into the sewer. Then, while the water is passing through the lower part of the flap, the sewer air will enter by the upper part, and thus the drain will be filled with sewer air, even while the water-traps are full. If one of the inlet-traps were unsealed, the air would pass through the unsealed trap instead of into the sewer. If the shackle-flap be the stronger resistant of pressure, the water poured into the drain will act on the surface of the water in the weakest of the water-traps, and impart to it a rocking motion, causing part of it to flow out of its basin. The atmosphere will also press on it, in the endeavor to take the place of the out-flowing water, and thus untrap the inlet, so as to allow the sewer air to enter the upper part of the shackle-flap during the period of flow. Then, if the outlet-trap be a common siphon, or the old form of dip-trap (which in principle are both precisely the same). then the sewer air will be entirely shut off, but the force of displacement of the contained drain air will most likely enter the house through the kitchen sink, as the air of the drains must escape somewhere, under the pressure of in-flowing water. In such a drain, the more water there is thrown into it, the more effluvia will escape. The slimy coating also of the interior of a long length of drain, is of itself sufficient to contaminate the contained air, no matter what fall the drain may have. In the methods just described, the one idea has been an unsuccessful endeavor to stop the opening from which the smell escaped, without inquiring if this or that opening is stopped, what will become of the foul air, what new state of things is produced, and what are the influences actually at work. Certain it is, that the more generally adopted of trapping inlet-drains favors the escape of sewer air into the houses.

Now, all that has been stated suggests that, in the trapping of drains, there must be provided—

1st. A ready and proper outlet for the escape of the drain-air when under pressure.

2nd. A means of supplying air to the drain, to follow the out-flowing water.

3rd. Such a construction of the inlet-traps as will effectually prevent the escape of drain-air.

The way in which these three principles may be applied is as follows: The outlet-trap is fixed at or near the point where the drain is connected with the sewer, and is made in one piece, with a siphon-dip, to shut off the sewer air, and an air-exit tube passing over the siphon-dip. Then, at the mouth of the air-tube a light metal air-valve is placed, so as to open outwards from the tube into the sewer on receiving a light pressure from within. Thus, when water is discharged into the drain, or a decided difference of temperature exists, the pressure of the air is exerted on the inner face of the valve, which then opens, and allows the drain-air to pass into the sewer. The siphon-dip, without the shackle-flap, is admissible at the outlet of a ventilated drain, as it is always charged with water. Then, at the several inlets are fixed valves to work freely, with siphon-dips behind them, excepting the water-closets and scullery-sinks. The valve shuts off the drain-air, whether there is water in the trap or not, and the siphon-dip prevents the escape of drain-air, during the period of flow, through the upper part of the valve. No amount of pressure from within the drain, or atmospheric influence from without, can affect the efficiency of these traps. Next, in any part of the drain (near the extremity is best) is placed an air-supply post, containing a light air-supply valve, which opens inward to the drain on a light pressure, so that when the water is emptied into the drain (having first displaced air through the outlet air-valve) flows out of the drain, it is followed by a supply of air through the air-supply port. The more water discharged into the drain, the more frequent will be the removal of air. In the application of this principle to a drain having inlets at a considerable elevation, in lieu of the air-escape at the outlet traps, an air tube is carried from the highest point of the drain to a height as far as possible from the windows and the influence of chimney down-draught. The inlets are secured by the same mode as that just previously described, a common siphon at the outlet, and the air-supply valve fixed near the outlet of the drain. By this mode a current of air is obtained from the lower part, passing through the drain, and discharging above the roof. In many instances air supply is obtained freely through the valve-sink inlets.

In the case of a house-drain connecting into a pipe-sewer, in order to obtain a ready access to the air-valve and siphon-dip, the air-tube is continued on to the surface side of the dip, where it receives a box, containing the air-exit valve. The air-tube thence continues down to the outlet side of the dip, and the air is discharged into the sewer.

The form of sink made for a garden-sink is adapted for yards, areas, stables, gardens, cellars, &c. A cheaper one for cottages is made in stoneware, with spigot-ends at the valve-mouth to fit the socket of an ordinary drain-pipe, and finished with a socket-flange at the top, to receive a perforated iron or stoneware plate; the workman laying the drain can thus complete his work without sending for the bricklayer, laborer, bricks, and cement, to form the receiver usually constructed beneath a bell-trap or 5-hole sink.

The form used for stables and large yard surfaces is made wholly of iron. An iron nozzle-piece is attached to the outlet, forming a spigot-piece, and is made to fit into an ordinary socket-pipe.

Scullery sinks are very difficult things to secure, because of the rapid accumulation of grease. Valves are inadmissible, except in the form of a gully-trap and receiver, which are found to be safe and effectual. The pipe from the sink should, in that case, be continued so as to dip into the receiver. In small scullery-sinks a deep form of garden-sink, without the valve, would be much cheaper, and is found to be effectual. The valve is also unsuitable for a closet-inlet, as the paper clogs the valve, and the siphon-trap of the closet is never dry, and is not subject to variation in a ventilated drain.

A few words on the subject of water-closets. It is as well to state some objections to the form of closet in general use. The well-known valve-closet, formed by a valve about 2 in. in diameter, closing at the lower part of the pan, is liable to leakage at the valve, and, when this occurs, the corrupted air contained in the iron chamber beneath escapes into the house.

A large number of copper and zinc pan-closets are in use. We have first the stoneware basin, then a swing pan of copper and zinc, then a large iron pan beneath these, and this iron pan has a surface of metal coated with foul matter equal to $4\frac{3}{4}$ ft., and in contact with the external air. The common closet-pan contains one-third of a foot super., but the most cleanly closet I have met with is one made by Mr. Jennings, which was in use at the last Great Exhibition, exposing a surface of $1\frac{1}{8}$ ft. only in contact with the soil, giving off the least amount of effluvia. A common stoneware pan is preferable by far, in the matter of cleanliness, to many of those costly contrivances that are in daily use.

In conclusion, the author hoped that the importance of this subject would be an excuse for the length of this paper.

COAL BURNING ENGINES IN ENGLAND.

In a series of articles on Railway Economy in "Herepath's Railway Journal," a history of the devices for preventing smoke and burning coal economically, is given, and the present practice is described.

The means that have been chiefly employed are extended fire grate surface, so as to have a thinner fire and afford a larger area for the passage of the air; and stepping or inclining the grate at a considerable angle, so that the coal being introduced close to the fire door, may gradually travel forwards as it parts with its gases and becomes incandescent, and thus ignite the gases that pass over it from the fresh fuel; making a double fire box with the same object; the application of a combustion chamber with or without fire-bricks, which become heated and ignite the gaseous products as they pass through or over them; and combined with these, various plans for admitting the requisite supply of air above the fuel, either by deflecting it as it passes through the fire door, or by introducing it through tubes or air passages.

Gray and Chanter in 1847 divided the fire box into two parts and admitted air above the fire. Dewrance improved upon this idea in 1845, and McConnell again in 1853, both these experimenters using the combustion chamber. The trouble, up to this time, was to ignite the gases distilled from the coal. In 1855 this was *perfectly* accomplished by Beattie,* but at the expense of maintaining and transporting some tons of fire-bricks. Cudworth's inclined grate came into some favor about this time. In 1856 Messrs. Dubs and Douglas applied a deflecting feather proceeding from the back of the fire-box towards the tube plate, to cause the gaseous products of the coal to descend on the incandescent fuel and thus become ignited, and Mr. Dubs, in connection with Mr. Evans, in 1857 added to this a movable inclined grate, which could be raised or lowered at will, for the proper management of the fire.

In 1857 Mr. Yarrow introduced a flat arch of fire-brick in the interior of the ordinary fire-box, placed at a considerable inclination, the lower side commencing just under the lowest row of tubes, projecting upwards until within eight or ten inches of the roof of the fire-box; tubes were also provided in the tube plate under the arch as well as in the fire-door for the admission of air.

The gases would thus be deflected, and have to pass round this brick arch, being at the same time heated and supplied with a fresh dose of oxygen from the air rushing in through the tubes. Considering that this was simply a modification of the fire-box originally designed to burn coke, the results were very satisfactory. A very similar plan was introduced by Mr. Jenkins on the Lancashire and Yorkshire railway, but in place of a fire-brick arch he employed a curved deflector of cast iron similarly placed, but perforated near its outer edge with numerous holes. He also employed air tubes at the front of the fire-box under the fire-door, as well as at the back under the tubes.

In 1857 Mr. D. K. Clark devised a system of forcing air into the fire-box through air tubes placed at the sides by fine steam jets directed from the outside and passing through the air tubes, which acting in a similar way to the blast pipe of the engine, caused currents of air to rush into the fire-box with great force. The orifice of the jets is but $\frac{1}{16}$ inch in diameter, the air tubes $\frac{1}{2}$ in. This simple arrangement was found to completely prevent smoke without any further appliance. It has been at work satisfactorily on several lines, and has been adopted on all the locomotive stock on the Great North of Scotland railway. Whether the steam which is introduced into the fire-box performs any office beyond the mere mechanical one of drawing the air in along with it, in producing any new chemical combination which would facilitate the combustion of the volatile gases, does not seem to have been investigated. It would, however, to some extent warm the air, and perhaps make good the loss from the use of the steam in this manner; and it is supposed that the steam has some power to precipitate the carbonaceous particles which remain unconsumed; at any rate the plan seems to be very economical. There is one advantage possessed by this plan over most others, viz., that by the use of these steam jets when the engine is in a station the smoke can be prevented, as they act in a more direct manner than a jet in the chimney.

In 1858 Mr. Wilson introduced a system

* See "European Railways," Colburn and Holley, for details.

of air tubes which extended from the fire-box right under the boiler to outside the front of the smoke-box. This arrangement would partly effect the object of Mr. Clark's steam jets when the engine was running, since the air would then be driven through these tubes into the fire-box with considerable force. Mr. Ramsbotham also about the same time provided two small doors in front of the fire-box, under the barrel of the boiler, with regulating valves for the admission of air above the fuel, and just above these openings he placed an arched fire-brick deflector, something similar to that of Mr. Yarrow.

Messrs. Lee and Jaques also introduced a somewhat similar arrangement as regards the projecting fire-brick arch, but they combined with this a deflector fixed to the top of the fire-door. This deflector projected into the fire-box sloping downwards, the door itself being underhung and provided with a valve for the admission of air, the opening and closing of which was regulated by a sector. The air being drawn in through the valve in the fire-door, would by means of the deflector be directed downwards, and mix with the gases, and their combustion be effected by impinging on the incandescent fuel, and the brick arch fixed against the plate.† About the same time Mr. Frodsham employed a deflecting plate over the fire-door, but the brick-arch was omitted, and in place thereof two steam jets were introduced, one on each side, into the front part of the fire-box, impinging downwards upon the fuel. Mr. Douglas employed a deflector with the same object, but he combined with it an inclined fire grate of larger area, which involved a longer fire-box, and of course necessitated an alteration in the boiler or the construction of new engines.

† This deflector in front of the fire-door, generally without the bricks, is now much employed in England with quite good results.—Ed. V. N. M.

THE LOCOMOTIVE OF THE FUTURE.

From "Engineering."

It would be difficult for the most enthusiastic engineering futurist, if at all practical, to point out the direction in which any radical improvement in the locomotive engine is to be sought. As long as the resistances opposed to the motion of trains are what they are, and as long as the present rates of speed are maintained, the amount of locomotive power to be provided cannot be lessened. There is not the slightest chance that any other agent than steam will be employed, in our generation at least, to produce this power. Compressed air locomotives, hot air locomotives, vapor of alcohol locomotives, and electro-magnetic locomotives have all been tried, and they have failed for perfectly obvious reasons—reasons which should have been foreseen by any one possessing the least knowledge of the motive agencies thus called into play. Steam, then, being our only resource, it can be generated only by the combustion of fuel, and this fuel must obviously be the cheapest available. With us, the cheapest fuel is coal. We can none of us see the way to anything cheaper. Petroleum may be burnt easily enough—its use is entirely practicable, but it is too dear. Even were it cheaper than coal, its use would involve no important constructive modifications of the locomotive boiler, and none whatever in the working machinery.

And what can be simpler than the locomotive boiler as it is. A large amount of heating surface *must* be provided, and how could it be better provided? There are few who would not desire to welcome improvements were they possible, but it will prove no easy task to improve upon the principles, or the construction, of Neville's multitubular boiler of 1826, as successively improved in detail by so many locomotive engineers since George Stephenson first brought it into practical work. The locomotive boiler has been made in almost every possible form. There have been twin barrels, double fire-boxes, round fire-boxes, combustion chambers, mid-feathers, return tubes, water tubes, water grates—indeed, every imaginable modification of the original structure to which all successful practice has again returned.

We have no doubt that steel will yet take an important part in locomotive boiler construction, as it has already done in that of fixed boilers. The Bolton Steel and Iron Company appear at last to have produced Bessemer steel boiler plates which can be thoroughly depended upon in large quantities, and there are fire-boxes of a somewhat kindred material—Howell's homogeneous metal—which have perfectly withstood nine years' use on the Scottish Central Railway. In all this, however, there is no new principle, and the most that can be hoped from steel, is somewhat greater economy in repairs, and the possibility of working higher pressures of steam, should it prove desirable to do so.

In the motive machinery of the locomotive, beginning with the regulator and ending with the driving wheels, no improvements beyond those of mechanical detail appear to be possible. No possible application of the principle of the rotary engine holds out the least hope.

As for the rest, the locomotive engine is a carriage merely. So much total weight, divided by so much permissible weight per wheel, and we have the necessary number of wheels, to be coupled or not, according to the requisite adhesion.

It is only as a carriage that we see much room for improving the locomotive. It does appear anomalous that with from one hundred to two hundred wheels beneath a train, none of them loaded beyond 3 or $3\frac{1}{2}$ tons, a permanent way of twice the strength otherwise necessary should be required to carry 7 tons each on a pair of driving wheels. It is equally inconsistent that with wheel bases of from 8 to 10 ft. under the wagons and carriages, from 15 to 18 ft. should be necessary for the engine. Were the maximum weight per wheel not more than 4 tons, and the maximum wheel base in any one unalterable rectangle no more than 10 ft., it is almost beyond dispute that a very considerable economy would be effected in the maintenance of the permanent way.

PATENTS.

The abolition of protection for inventions has frequently been discussed in England, but the late advocacy of such a step in parliament, and by persons of importance and influence, has created an unusual excitement among the classes most interested, which has found copious expression in the London scientific press. For a government to broadly declare that the rights of property in inventions should cease, would be as foolish and suicidal as to broadly declare that there should be no property except in material, tangible things—that the intangible results of one man's mental labor should be the property of all men. Under such a law few inventions would be made, simply because they could not be protected. Successful inventions, that benefit mankind and advance civilization, are almost invariably the fruit of costly experiment. The first ideas of the greatest inventors are crude. Watt, Bessemer, Morse, Goodyear, Ransome, Howe, Corliss, Roberts, Siemens, Ericsson—none of these men perfected their works at the start. Their success is due vastly more to their persevering warfare against "practical difficulties"—to the pluck and business capacity of themselves and their partners, than to their original discovery or combination of certain materials and forces. Is it reasonable to suppose that Bessemer, for instance, would have worked for five years against all manner of difficulties, and at a cost to himself and associates, of many thousands of pounds, to make the pneumatic process a success, if the sole fruits of his brain and fortune were to be then snatched out of his hand, without one penny of compensation? Yet, just that labor and fortune had to be risked by somebody, or the pneumatic process would have been perfectly impracticable and useless. Inventions cannot be protected by being kept secret—there is no use in arguing this point—and if they were kept secret, how far would the public be benefited by them? If the patent laws are abolished, all the men who have the capacity and means to *work out* great improvements, will have to do so at their own expense, for the benefit of their rivals in business, and without hope or right of reward. When business men present one another with checks and pig iron and cotton and farms and machinery, inventors may be expected to work without protection. In short, if the patent laws are abolished, the stimulus to working out inventions and making crude ideas practicable, will be taken away—there will be no farther reason why men should invent, and they will stop inventing. They may, indeed, start ideas, generally undeveloped, but they will not and cannot, on any other ground than general philanthropy, undertake the cost of making their ideas practical and useful, and this is what the law recognizes as the subject of a patent.

Only two apparently reasonable grounds of objection to property in inventions have been put forward. The first is, that only one in a hundred inventions is useful. Well—is the public injured because a man obtains a patent for a useless invention, any more than it would be if he spent the same money on a useless building? In the former case he neither creates *nor destroys* any value. But it will be said that the inventor of a useless machine "ties up" combinations and parts which another man could, if they were free, make useful. Nothing could be more at fault than such a statement. The patent law contemplates a machine that will perform the functions claimed. If it will not, the patent is invalid, and the parts and combinations *are* free. If it will, and the functions are desirable, then the invention is not useless, and the inventor is entitled to just what he invented—no more. If another inventor makes an addition that enlarges or betters the functions, or cheapens the operation, he is entitled to just that improvement—nothing more—and the parts and combinations that are tied up by the first patent, are no more unfairly tied up than the first inventor's house and shop are—they do not belong to the second inventor—he found them the possessions of another.

"But says the objector—"Many patents claim more than they can accomplish—the *untying* of parts and combinations thus involved is a tedious and costly process of law." This is true, but the embarrassment is the inventor's, not the public's. If inventors are willing to go to such cost to establish their claims, the public is not only uninjured by the process, but it is largely benefited by the result. Suppose that property in patents were unlawful, so that inventors could not test the validity of their works in the courts, and would have no inducement to do so if they could—how much better off would the public be then? They would not, indeed, have to pay any royalty to either contestant, nor would there be any improvement to use. They could reap by hand and go on foot at ten times the cost of machinery, and save a small fraction of their loss by not paying royalty.

The main argument against the patent laws is, that where the public possesses, in common, all the elements of the knowledge out of which an invention may proceed, it is unjust that he who happens to have a week's or a month's start over his fellows in arriving at an important practical application of that knowledge—an application which, it is assumed, scores of others are seeking, and which, it is furthermore assumed, some of them would, in a short time, have certainly attained—it is unjust, the argument repeats, that the first one who finds out what others *might* have found out, should be permitted to block up the road against them. In answer to this, "Engineering" says: "In other words, although the world had waited six thousand years or so for a given invention, it was certain that a dozen or more inventors were as near to attaining it at a given time as would a dozen competing horses be near to the winning post at Epsom within five seconds of the finish. All this is merely begging the question, if it be not, indeed, a mere display of idle sophistry."

This objection, furthermore, shows the gravest ignorance of the history and probabilities of patents. As we have before stated, useful inventions are in the rarest instances, if ever, complete and perfect inspirations. An idea—for instance, the idea of the telegraph, or of the pneumatic process, may be instantly conceived—but undeveloped ideas are not the subjects of patents. Before the law recognizes them, they must be clothed in working bodies, so that the law can see that they will perform the functions claimed. Now, the ideas of decarburizing cast iron by air and by ore, were not only known a century ago, but were practiced before the reader of this paper was born, and have been, in various partially-developed shapes, patented from time to time for years. Surely we have all had not only an untrammeled chance to invent the Bessemer and the Ellershausen processes, but we have had a very close guidance to them in the experiments and practice that preceded them; and we can no more fairly quarrel with the law that protects them to Bessemer and to Ellershausen, than we can with the law that keeps our hands out of the strong-boxes of Stewart and Vanderbilt. We have had just as fair a chance, under the law, to make the fortunes of the latter, as we have had to make the inventions of the former.

But above and beyond the *policy* of protecting patents, there is the question of *right*. Upon this Mr. Greeley says in his political economy, now in course of publication: "The rights of those who create intellectual property are less clearly defined — perhaps less capable of unerring definition — than those of the producers or transformers of material substances; yet they seem to me not less real, beneficent, and defensible. Let us suppose that four brothers commence responsible life with equal patrimonies, equal capacity, and like habits of industry, temperance, and frugality. Twenty years afterward, one of them, who has devoted his energies to farming, has a fine estate, a commodious dwelling, a handsome herd of cattle, a good collection of implements, a library, and all the material elements of independence and comfort. A second has addressed himself to the construction of locomotives, and has done as well thereby as his farming brother. A third has given himself up to the study of mechanics and engineering, and has, after many disappointments, perfected a new steam-engine, whereby the power required to move a train or boat of so many tons, at a given rate per hour, is reduced at least twenty-five per cent. The fourth has addicted himself to literature, art, and poetry, and has produced a book which one hundred thousand of our people annually read, deriving pleasure and instruction therefrom which they would rather pay him for than forego. I ask why this inventor, and this author, have not as fairly earned, and are not as justly entitled to, the price that others prefer to give rather than forego the advantage or pleasure derived from their products, as are their brethren, the farmer and the locomotive-builder, to a like remuneration for the use of *their* products? If, as Thiers forcibly says, 'The indestructible foundation of the right of property is labor,' then, surely, the right of property in Elias Howe to that combination of the needle with the shuttle which gave practical existence and value to the sewing machine, of Alfred Tennyson to 'The Princess,' 'Maud,' 'In Memoriam,' and 'The Lotus Eaters,' is as perfect as any right of property can be. For the craftsman merely fashions, adapts, or recasts, materials co-existent with the earth, and which may be regarded as in some sense once the common property of mankind; while the inventor, the poet, builds into the void space, makes chaos luminous, and adds potentially, and as it were by original creation, to the enduring wealth of mankind. I cannot perceive how or why his right of property in his products is not at least as perfect and pervading as that of the maker of a locomotive, the grower of grain.

"I have considered what has been urged in favor of a restriction of this right of property to the material thing wrought upon—to the particular locomotive built by the inventor, the author's manuscript copy of his poem—and it seems to me palpably absurd. For what the inventor has labored twenty years to perfect is not the single, particular locomotive on which he expended his handiwork, but *all* locomotives to be thereafter built—his efforts were incited and upheld by a desire to make *all* locomotives henceforth less costly or more efficient. This he has achieved, or nothing; herein he has succeeded, or not at all. Once completed, the machine whereon he has labored so long may accidentally take fire and burn to ashes, yet no one, surely, would thence infer that his labor had been in vain.

"As to the abolition of the patent system, which has of late been influentially advocated, I shall be more easily reconciled to it when I learn that it is to be swiftly followed by a repudiation of *all* rights of property whatever—or, more strictly, of all legal guaranties and defenses of such rights. Whenever the laws of my country shall refuse to protect the inventor, they should, in simple consistency, bid the land-owner, the bond-holder, the merchant, the banker, 'Take care of yourself, and of all that you call your own!' Assuredly, no man's right to the wild lands conceded to his ancestor by a European monarch who never saw, and knew not how, even to bound them accurately, can be better than that of Eli Whitney was to his cotton gin, or that of Daguerre to photography. When these shall be successfully denied, be sure that *no* rights of property can be secure.

"'Then, why not make patents and copyright absolute and perpetual?' is often asked. I answer, there are *no* absolute rights of property. The land you bought of the Government yesterday may be taken from you for the bed of some highway or railroad to-morrow, and you have no redress. *All* rights of property are held subordinate to the dictates of national well-being; and the Government will batter down or burn to ashes your house, if it shall have become (through no fault on your part) a harbor or defense of public enemies, and make you no compensation therefor. I only insist that intellectual property shall be recognized by law as standing on a common foundation with other property and equally accorded the protection of the State and the respect of all who hold property no robbery, but justly entitled to deference and support from the wise and the good."

In the discussion of this subject "Engineering" reviews, at some length, the more important inventions now in successful use, and they are of a thousand times more value to the public than to the inventors, large as the aggregate royalties must be. We quote the remarks of our cotemporary, not only to show how little legislators and anti-patent law agitators, like Sir Roundell Palmer (to whom these considerations are addressed), are likely to know about what they are talking, but also to remind the profession and inventors of the greatness of the field in which they are called to labor, and of the inspiring success already achieved.

"Of modern inventions there are, literally, hundreds which, we have reason to believe, would have failed to establish their value to their authors, and especially to the public, but for the protection of the patent laws. Of hundreds of these, we firmly believe Sir Roundell knows absolutely nothing at all, and this, although many of these very inventions have received his own fiat as Attorney-General. Were it possible for him, and, we will add, for Lord Stanley as well, to leave, for a week, the oppressive atmosphere of politics and law, and devote one-half of that time to a rapid survey of recent successful inventions, both would form views very different from what they expressed in the House of Commons last Friday evening. Each pitched upon the steam engine, the electric telegraph, and the screw-propeller as distinct substantive inventions; and yet it is absolutely impossible to say who 'invented' either of them, although it is easy to name from half a dozen to a score of inventors, in the respective cases, who contributed greatly to the success of these inventions, and each of whom deserved, so that his claims were justly and exactly specified, such reward as a patent best affords. To any one who knows the history of these great inventions, it is absurd to say that James Watt, Professor Wheatstone, and Mr. Francis Pettit Smith were THE respective 'inventors,' although, in each case, they opened more ground, and to better purpose, than any inventors who had preceded them. James Watt, taking the steam engine in the imperfect, but yet effective, state in which he found it, invented the separate condenser, the steam jacket, the parallel motion, the sun-and-planet motion, and other details, and in his best practice his engines consumed 10 lbs. of coal per indicated horse power per hour. At the present time, non-condensing engines, the 'invention,' possibly, of Trevithick, work without separate condensers, without steam jackets, without parallel motions, and without sun-and-planet wheels, with a consumption of but from 3 lbs. to 4 lbs. of coal per horse power per hour. To enumerate the patented meritorious improvements in the steam engine would require much space, but Sir Roundell Palmer would find no difficulty in obtaining a knowledge of them were he to place himself in communication with any of our leading mechanical engineers.

"In other branches of engineering the modern, patented, *meritorious*, inventions are so numerous that it is difficult to bring them within the limits of a catalogue *raisonné*. We might mention five hundred as easily, but for limits of space, as one hundred, and as it is certain that none of us know the full width of the field of invention, there are probably other hundreds of valuable inventions of which a single writer may be ignorant. Again, for the principal patents obtained for important inventions many subsidiary patents are granted for details useful in working them, just as the 'Bessemer process' is protected by, in all some dozen of patents, each of which possesses a certain value, and is therefore meritorious.

"It would be a long list were we to record the modern meritorious inventions relating to the manufacture and working of iron. Quite apart from the more recent and suspicious patents obtained by Heaton, Radcliffe, and Richardson, and on the other hand apart from the grand series of patents in Bessemer's name, there are, among patents, in force or lapsed, Siemens' furnace, which melts iron of any quality as if it were wax; Aitken's kilns for coking carbonaceous ironstones; Bourdon's (Morrison's) coal-washing machine, whereby excellent coke is made from the most sulphurous refuse known as coal slack; While's continuous blooming mill; the steam hammer; the self-acting steam hammer; Ramsbottom's duplex steam hammer; Davies's steam striker, the most pliant, adaptable and intelligent steam hammer yet contrived; Ryder's forging machine, as effective as it is noisy; Haswell's, and Shanks', and Kohn's hydraulic forging presses; Garforth's steam riveter; Bertram's admirable system of gas-welding boiler, beam, and girder plates, so well worked out by the Butterley Company; Root's blower, the finest blast engine for foundrymen yet schemed; Woodward's steam jet cupola, which dispenses with mechanical blowers of every kind; Jobson's, Howard's, and the Anderston Foundry Company's systems of machine moulding; Hetherington's system of plate moulding; George Scott's superlatively beautiful system of mechanical wheel moulding; Deakin and Johnson's process for punching steel tubes—a process which, when we reported that a $10\frac{1}{2}$ in. hole had been punched 4 ft. deep through a 3 ton ingot appeared incredible to many of our readers; Hawksworth and Harding's even more wonderful process of cold "drawing" steel tubes, of any and every section, from hollow ingots; and, finally, Westwood's hydraulic press for bending the thickest armor plates, even up to 14 in. thickness. Were it not that Sir Roundell Palmer and Lord Stanley had delivered themselves so authoritively upon the whole range of invention, we should not have presumed to ask them how much they know of any one of the inventions we have mentioned. Unless "coached," we will venture the assertion that, if examined, competitively, they would both be found absolutely ignorant of nearly every one we have named, and yet each of these patents deserves, and properly managed, is likely to realize what either Lord Stanley or Sir Roundell Palmer might consider a very handsome fortune. And without the protection of a patent no man of business, in his senses, would care to work them at all, unless *en amateur*.

"Then there is another wide class of inventions relating to railways and railway rolling stock. There is the fish-joint—Mr. Bridges Adams's fish-joint after all the hubbub raised about it eight years after the expiration of his patent; the cast-iron pot sleeper (poor Greaves!) Ransome's and Vickers' crossings; Arbel's stamped wheels; Mansel's wood wheels; Beattie's clip fastening for the tyres; half-a-dozen oil-tight boxes; Clark's and Fay's continuous brakes; Sterne's capital buffers; Saxby's signals, which, we sincerely believe, have, by this time, saved the lives of ten thousand of Her Majesty's subjects; Ransbottom's trough for supplying tenders while on the way; ditto, his safety valve, and, ditto, his lubricator, both good things of their kind; Naylor's excellent safety valve; Bourdon's magnificent invention, though after all akin to Salter's balance, for weighing steam; Giffard's dynamic paradox, known as the Injector, and Schau's simpler and cheaper edition; Green's useful invention for drawing tubes from brass, and, finally, an invention of great intrinsic worth—Dudgeon's tube expander. How much do you know of all these, or any of them, Sir Roundell? Don't think us impertinent.

"Turn which way we may, we find almost innumerable recent, meritorious patents. In civil engineering we have Mitchell's screw pile, which has saved untold thousands of pounds in the cost of fixing uncertain foundations in India; Dr. Pott's system of pneumatic sunk cylinders; Hoffman's annular kilns for burning bricks; Dennet's fireproof flooring, now adopted in all the principal buildings in progress in the kingdom; and Clayton's well-designed machinery for brickmaking.

"In stone-working we have (and we should be sorry to be without) Blake's stone-breaker; Holmes's stone-dressing machine; Ransome's grand invention of artificial stone — an invention possibly worth more than Columbus' discovery of San Salvador; M. Sommelier's (*Anglice*, Mr. Butler's) tunneling machine; and, finally, Mr. Doering's and Mr. Lowe's machines for the same purpose.

"In connexion with the cotton manufacture less can be said. It is an industry which admits of but moderate progress, unless some new Hercules comes to our aid. Mr. Richard Roberts *was* a Hercules in this branch of engineering. There are Wellman's self-stripping cards; Leigh's top rollers; Hetherington's wonderfully simplified mule; the Blackburn "Slasher;" Messrs. Harrison's astonishing improvement upon all the space, tediousness, dirt, and cleaning of the dressing machine that had gone before it; and, finally, Bullough's loom patents, which have added a million of money to the wealth of Lancashire. To these may be added, with a qualified opinion of their merits, a nameless number of cotton gins; and in this and kindred branches of invention, there is not so industrious a patentee as John Platt, M. P., whose authority is quoted against patents, but who is, himself, an insatiate patentee, as well as an enterprising appropriator of ideas, supposed to be covered by patents in other men's names.

"Then comes the old class of patents relative to grinding flour. First there is the decorticator, worth a million in good hands; but, possibly, before it, the grain drier, upon the results of which so many fortunes hang. Again, there is Bovill's patent, renewed, against which so many millers fought, and to which so many surrendered. Then there is Golay's diamond machine for dressing millstones, sold for ever so many thousands of pounds, Brackshaw's grain elevator, and, going back for some years, Goucher's capital beaters for thrashing machines.

"In steam-agriculture there have been such improvements that we hardly know how to begin. The grand brain who did more for steam cultivation than any thousand men now living was John Fowler, long since in his grave. Sir Roundell Palmer, we presume, would, were it in his power, annihilate the industry growing out of Mr.

Fowler's inventions. His steam plough, his clip drum, his slack gear, are all unique, and long settled practice has proved that their value might be counted rather in millions than in thousands. And no industry he had to fight harder for existence: fights of which Sir Roundell probably knows nothing at all, for, had he known of them, he could not, as a gentleman, have spoken as he did last Friday evening.

"Then, again, in connexion with steamships. There are Cunningham's self-reefing topsails; Trotman's anchors; Clifford's boat-lowering apparatus; McFarlane Gray's steam steering gear; Robert Griffith's big boss, two, or three-bladed screw propeller; the engine-room indicator; Morton's ejector-condenser; Robertson's ashes ejector; and, to go from little things to great, Penn's trunk engines, and, of far more value than anything else ever invented in connexion with the screw engine—wood bearings—one among the grandest inventions of the present generation.

"Again comes another class of invention, viz., those for lifting and hoisting. Among these Edwin Clark's hydraulic graving dock stands first in importance; and, next to that, the various plans for hydraulic jacks, as well as Weston's pulleys, and the derrick crane made by Bowser and Cameron.

"But among the valuable miscellaneous patented inventions who shall draw the line? There are the patents for Dr. Dauglish's aerated bread; the American sewing machines; Anglo-Franco velocipides; Chappuis' daylight reflectors; Bunnett's coiling shutters; Betts' capsules; Wheatstone's private telegraph; Wheatstone's crytograph; Richards' indicator; Dunbar's apparatus for charging and drawing gas retorts; Perin's band saw; Chatwood's safe; dozens of inventions of breech-loading rifles; the Manchester water meter; Bailey's oil tester; a lot of American inventions for gas regulation and gas carburation, as well as for tin-lined lead pipe, the latter manufacture based upon the "flow of solids," commercially worked some years before M. Tresca's ingenious researches at the *Conservatoire des Arts et Métiers*, in 1866. There is the magnetic anti-incrustator, Siemens' gyrometric governor, Mallet's buckle plates, the Abyssinian tube well, Lloyd's fan, Robertson's frictional gearing, Dellagana's paper stereotype moulds, Gaine's parchment paper, Young's paraffine oil patent, Moncrieff's gun carriage, Hugon's gas engine, Armstrong's beautiful dove-tailing machine, Robert's elegant "diffusion" process for making sugar, Seyrig's centrifugal machine for drying sugar and other substances, the revolving magnetic machine for separating iron from brass turnings, Needham and Kite's yeast press, Harrison's ice-making machine, Carr's beautiful disintegrator, Peet's valve, Chatterton's compound for submarine cables, Webster's ferro-zinc paints, Moule's earth closets, Liernur's sewage system, Sillar's precipitating compound for sewage, Worssam's silent feed, Palliser's bolts, Batho's nut shaper, Sellers' bolt cutter, Perkins' sealed heating pipes, Porter's governor, Armstrong's hydraulic machinery, coal cutting machinery, Upward's drilling apparatus for gas mains, Garside's electograph engraving machine, Livesey's newspaper folding machine, various excellent refrigerators, King's malt measurer, and so on, in an almost endless list.

"Valuable as these inventions are, it has required a vast aggregate expenditure of time and money to induce the public to believe in, and adopt them. None, assuredly, knowing the task would have undertaken it without some hope of substantial reward, and patents appear to be the only rewards available. The inventions enumerated bear no proportion in number to the hundreds of useful modifications and combinations of modern machinery which are valuable rather for their simplicity and convenience than for any distinctive mechanical principle."

MARINE ENGINE PROGRESS.

From "Engineering."

Not middle-aged engineers alone, but comparatively young engineers as well, have had occasion to remark the wonderful rapidity with which the marine engine practice of any given period may become obsolete. The grand old side-lever engines of twenty years ago, or for that matter ten years ago, are fast becoming curiosities possessing a high degree of archæological interest. It will not probably be long before the 100 in. cylinder, 12 ft. stroke engines of the Scotia, only finished in March, 1862, will be replaced by screw engines, as has been done already in the case of the Persia. We have only to look back to 1847 to find but 156 steamers built and building in the British Navy, none of them exceeding 1862 tons, or 800 nominal, equal only to about 1500 indicated, horse power. The Greenock, the

Phœnix, the Rattler, the Fairy, the Bee, and the Dwarf were the only screw vessels, although the Amphion, Arrogant, Conflict, Dauntless, Desperate, Encounter, Euphrates, Megæra, Minx, Niger, Rifleman, Sharpshooter, Simoom, Termagant, and Vulcan—all screws—were in progress.

There is little reason to doubt that the opinions of marine engineers were as fixed and as strong, in 1847, as they are now, and then it was then believed that science and skill had done well nigh all that was practicable for the improvement of the marine engine. The steam was low and the speed was slow; the former from 5 lbs. to 10 lbs., the latter from 140 ft. to 260 ft. of piston per minute. The Alecto with 4 ft. 6 in. stroke, made but 14 revolutions per minute in regular work, or 126 ft. of piston, and even the Avenger, with 650 horse engines, 6 ft. stroke, made but 13 revolutions or 156 ft. of piston per minute. The Dee, with 200 horse engines, 5 ft. stroke, made but $12\frac{1}{2}$ revolutions, or 125 ft. of piston per minute. The Thunderbolt, with 300 horse engines, 5 ft. stroke, made but 15 revolutions, the Salamander, with 220 horse engines, 5 ft. stroke, made but 14 revolutions, and even the Victoria and Albert, with her original 400 horse engines, 6 ft. stroke, made but 17 revolutions of her 30 ft. wheels, corresponding to but 204 ft. of piston per minute.

There were many who disbelieved in the screw altogether, and its introduction into war ships was partly if not greatly due to the circumstance that the screw engine and propellor could be kept wholly beneath the water line, and that the deck was left clear for its whole length for armament. As for merchant steamers, it was long before steamship owners would listen to any arguments in favor of the screw.

It was even doubted whether screw engines could be practically worked at the high speed required by the screw, and gearing was often employed, as in some cases it is still. With injection condensers, and the old forms of flue boilers, steam of more than 10 lbs. per square inch was considered out of the question at sea; expansion was seldom practiced to any extent, and superheating was reckoned a costly and needless refinement, if, indeed, it had been thought of at all. The whole ground opened by the introduction of the screw was beset with difficulties, and but few were willing to believe that these could ever be overcome. The screw vibrated greatly, and came well nigh shaking the stern post out of the ship, and it was next to impossible to keep the screw shaft tight in the stern tube. Direct double-acting, full stroke air pumps, too, knocked their valves to pieces very quickly.

Marine engine improvement has consisted in doing just what twenty years ago was reckoned impracticable or inexpedient. The tubular boilers that were to give so much trouble by salting and leaking are now in universal use, and a flue boiler of 1850 would be reckoned a curiosity. The pressure of steam has been carried to 25 lbs. or 30 lbs. in regular work, while Mr. Elder's boats, and the Sirius, engined by Maudslay, are worked to 50 lbs. The piston speed has been carried, as a maximun, to 600 ft., and even 650 ft. per minute. Indeed, Mr. Bourne once worked a single cylinder engine of 3 ft. 6 in. stroke at 100 revolutions per minute. Superheating is now practiced with advantage and a good degree of expansion attained, in some cases with compound, or high and low pressure engines. Surface condensation, with all the cost, weight, and bulk of the tubes, and the difficulty, once encountered, of keeping them tight, as well as the danger, at one time so imminent, of corroding the boilers, is now a firmly established fact. Double-acting air pumps, making 75 double strokes, and 600 ft. of bucket per minute, work as easily and silently as the old air pumps, worked, off the beam or side-lever, at 80 ft. or 100 ft. with only but 15 or 20 double strokes per minute. The vibration of the screw has been well-nigh stopped by Griffiths' improvements; its stern bearing is now the most durable of all, since Mr. Penn applied wood bearings and the dynamic performance of large screws of fine pitch is in all respects equal to the best results obtained from paddles, while the machinery required to drive it is, of course, far lighter in respect of weight. Were we now to return to Boulton and Watt's old practice of 7 lbs., effective cylinder pressure per square inch, and 204 ft. of piston per minute for a $4\frac{1}{2}$ ft. stroke, it would require a pair of engines of 29 ft. 6 in. (354 in.) cylinder to develope the power of 8,500 horses, indicated on the trial of the Hercules. The revolutions would be $22\frac{2}{3}$ only per minute, requiring gearing in the ratio of about $3\frac{1}{4}$ to 1 to get up the 72 revolutions actually attained by the Hercules' screw. No comparison possibly could better mark the progress already made in marine engines. But if we address ourselves to an inquiry as to the limits of further improvement, we are confronted by seeming impracticability or impossibilities, such as stopped the way twenty years ago. To what point may the pressure be yet carried in practice? To 100 lbs., or more? Rowan worked 130 lbs. at sea; but his boilers gave trouble. Of course, with very high steam, superheated and condensed after exhaustion, a rate of expansion of 12 or 16-fold is practicable. As for piston speed, it may, possibly, be yet increased to the rate occasionally attained in locomotives, say to 900 ft., or even 1,000 ft., per min.; but we are all disposed to be incredulous as to the continuance, and especially the economy of such speeds. But, as abstract facts, we do know that steam engine economy is to be sought in high pressures, high speed, and high expansion.

It is a question whether the hot gases escaping at the chimney might not be advantageously forced into the boiler, below the water line, and be thus made to give off their heat. For every ton of carbon burnt from 6 to 7 tons of water are evaporated, while, also, $3\frac{2}{3}$ tons of carbonic acid are sent up the chimney at a temperature of perhaps 600°. That there is a considerable loss here is indisputable. The only question is, how may it be prevented, the presumption being that the cost of securing this waste heat would be greater than it would be worth when saved. Air, too, forced through a heating apparatus into the water in the boiler, or into the steam, would possess a theoretical advantage, and we hear of one or two patentees who are already experimenting in this direction, among them Mr. Richard Eaton, of Nottingham.

STEAM ON CANALS.

PROPULSION BY A FIXED WIRE ROPE AND CLIP-DRUM — EXPERIMENTS IN BELGIUM.

From "The Engineer."

A series of highly interesting experiments, or rather a general exhibition of the first line of considerable length, on which a new principle—the application of wire rope and clip-drum for river navigation — has proved practically successful, took place on the 4th and 5th inst. between Liège and Namur, in Belgium. The governments of England, France, Prussia, Austria, Wurtemberg, Holland, and Belgium, sent their special engineers; the Suez Canal Company, and steam navigation companies from the Danube, the Elbe, the Rhine, and the Rhone, were represented, and the presence of gentlemen from almost every country in Europe proved the importance which must be attributed at the present moment to all successful improvements in the methods of inland navigation on rivers and canals.

The Meuse has, between Liège and Namur, a length of nearly seventy kilometers (forty-four miles), leading through one of the principal coal districts in Belgium. The river forms one of the most important links of the long chains of canals and streams which connects Belgium, and particularly Antwerp, with Paris. A company, the Société Anonyme Liègeoise de Tonage, received a year and a half ago the concession for supplying the system patented by Bon. C. de Mesnil and M. Eyth to this line, and began their operations by laying an iron wire-rope of 1 in. outside diameter on the bed of the river. There are eleven locks to pass, which do not interrupt the continuous length of flexible rail thus placed in the axis of the whole water-course. Small holes are provided in the gates near the sill, so that the wire passes through the locks without interruption, and the gates being opened are perfectly free to be moved by the machinery. The only places where the rope is actually fixed or moored are two temporary ends at Liège and Namur, everywhere else it follows in a comparatively slack state all the bends and curves of the center line of the river. The mechanical principle of the system now consists in mounting on the tug-boat which carries the machinery a clip-drum, vertical or horizontal, which takes hold of the rope, the boat taking it up from the river bottom by suitable pulleys near its bow, and dropping it again near the stern into the water. The clip-drum, turned by the steam machinery, will thus haul the boat along the so-called fixed rope, pulling, in fact, on the weight of the wire and the frictional resistance of the same on the river bottom. In principle, therefore, the idea is the old one of chain navigation, as applied during the last twelve years or so on the Seine. But the practical difficulties which prevented the more general introduction of the latter, in spite of the great advantages inherent in the principle, are avoided in the new methods to so considerable a degree that M. Eyth's system seems to be destined to raise again inland navigation to the relative importance which its physical peculiarities warrant, and which it has, in most cases, lost by the introduction of railways.

The first tug of the Société de Tonage started on the line on which the experiments took place about a year ago. It is an iron boat, flat-bottomed, of twenty meters length, four metres width, 2.25 meters depth of hold, drawing 0.95 meters, and carrying a 14-horse power horizontal, double-cylinder, high-pressure engine. This engine works a vertical clip-drum on the side of the boat, of 6 in. diameter, over which, by means of two guide pulleys of the same diameter, the wire rope takes half a turn. The machinery was constructed, like that of the greater number of cable tugs now in Belgium, in England, by Messrs. John Fowler & Co., Leeds, who have made the construction of this sort of boats one of their specialities.

The speed of the clip-drum can be altered by suitable gear, thus giving ten, five, and two and a half kilometers, or rather more than one and a half miles per hour, to the tug. The first was intended to be used in towing down stream; but it was found that, with long trains in sharp bends, it could not be worked safely, and that the speed exceeded the requirements of the trade. The gearing proper to it was therefore removed. The speed of two and a half kilometers is only used in winter, for towing up-stream in the most rapid currents, which may amount, in certain places of the river, to ten or twelve miles an hour. The greatest amount of work done by this tug is, if going up-stream, at the rate of four miles an hour against an average current of two or three miles. Working with the full power of two 7¾-in. cylinders, 12 in. stroke, seventy revolutions, 80 lbs. or 90 lbs. pressure, it towed 1,500 tons of freight, as taken in ten boats of varying burdens; also, on another occasion, 1,000 tons of freight in eighteen boats more or less freighted. During winter the tug worked against currents, which the 45-horse power passenger steamers of Seraing were not able to overcome; 400 to 500 tons freight were taken in three boats, with the speed of two and a half kilometers, keeping thus the navigation open during a season which, up to now, was considered lost for the boat interest of the Meuse.

In consequence of the great delays at the locks, if towing considerable trains, the average mileage of the tug per day is small, amounting only to about forty-five kilometers, and being about double of what is done by horse towing on the same line. But the Belgian government, being satisfied of the beneficial influence this enterprise already effects on the movement of the river, have now decided to increase the dimensions of the locks, so that in future a whole train will be locked through at a single operation. So the mileage may be raised in future to fifty or sixty miles a day easily.

The coal consumed per day of ten hours was about half a ton, the ton costing 11½f. on the boat. There are five men on board, a captain or pilot, two sailors, an engine driver, and a fireman, and the total monthly working expenses amounted to about 600f. (£24). In towing 800 tons thirty-five kilometers per day, which may be considered at the present moment an average performance of the tug, the daily receipts are under the present tariff of 0.006f. per ton and kilometer (about one-third cheaper than horse towing for hire), 168f. Now the tug requires two days to go the seventy kilometers from Liège to Namur, and comes back frequently empty in one day. It has, therefore, twenty working days in the month, which pay, and the whole monthly receipts (if nothing is to be towed down stream), are 3,360f. (£134). Three more tugs are now in the possession of the company, of which two were successively tried during the experiment. They worked, especially in the sharp bends and considerable currents above Seraing, with regard to hauling and steering, with a steady ease which left nothing to be desired. It was generally feared that sharp bends with strong currents would be fatal to the system. These tugs are five meters longer, carry engines of 20-horse power, and differ in their constructive details considerably from the original type. They are all provided with an auxiliary screw, so that they can moor independent of the rope if required. This gave, some weeks ago, an opportunity of carrying out a very interesting experiment. The whole power of the engine can be brought to bear on the screw, and in that case the propeller was able to tow a 250-ton boat against the average current of the river, but no more. Working by means of the wire rope, she towed with ease five times as much at the same rate. It must be said that the form of the tug and the dimensions of the screw are not the most favorable for the propeller, and some 20 or 25 per cent more might be got out of more suitable proportions. Still, taking in account everything in this direction, there remains an effect of the engine about three times greater when working with the clip-drum than if using the screw.

Besides the line on the Meuse, there are now wire ropes on the Canal de Chaleroi, in Belgium, on the Canal de Beveland, in Holland, and on the Canal de Terneuze, which connects Ghent with the Schelde, and a short experimental rope for the Rhine. Considering the short time the idea has had for its practical development—the first experimental machinery being made in Leeds in 1866—these results speak for its importance and the undoubted success it has obtained on the lines in actual operation.

THE MANUFACTURE AND USE OF PORTLAND CEMENT.

BY DR. W. MICHAELIS.

Condensed and translated from "Polyt. Centralblatt."

Cements may be divided into two classes, the Roman cements and the Portland cements. The Roman cements are made from earths found ready in nature, especially in the Jurassic rocks. Their name was given to them by Parker, who was the first to use the limestone nodules of the island of Sheppey for the preparation of a water-mortar or cement, which is very similar to the mortar made by the Romans from puzzolana. Portland cements are generally water-mortars that are prepared artificially by grinding and mixing different natural substances. When hardened, they resemble in color and durability the celebrated Portland stone. They have, therefore, been designated by the same name by Aspdin, the inventor of the first artificial cement.

The principal distinction between Roman cement and Portland cement lies not, however, in their origin, but in their different physical condition, caused by different methods of calcination. Roman cement is a fine dust-like powder, partly of a light, partly of a dark reddish-brown color. It absorbs carbonic acid and water eagerly, and cannot, therefore, be stored for a long while. Portland cement, on the contrary, is a powder consisting of fine crystalline scales of a dark-grey, somewhat greenish, color, much heavier, absorbing carbonic acid and water less rapidly, so that it may be stored for some time. It is calcined at a considerably higher temperature than Roman cement.

Portland cements are considered the best water-mortars. Being artificially prepared, they can be obtained more homogeneous and uniform than the Roman cements, which vary too much in their composition.

The following analyses of some Roman and of some Portland cements show this distinctly:

ROMAN CEMENTS.

	1.	2.	3.	4.	5.	6.
Lime	58.38	55.50	47.83	58.88	68.8	78.31
Magnesia	5.00	1.73	24.26	2.25	2.3	3.60

Magnesia	.82	1.14	1.15	.23	......	2.24	.77	1.35	1.64
Potassa	.73	} 1.27	.77	.94	......	.60	1.13	.59	.77
Soda	.87		.46	.30	......	.40	1.70	.71	......
Sulphate of lime	2.85	1.30	......	1.52	1.530	1.64	1.75	1.11	3.20
Insoluble clay and sand	1.47	2.54	1.32	1.04	1.28	1.13	2.27	......	1.08

ORIGIN OF THE ABOVE ROMAN CEMENTS.

No. 1. From a triassic limestone near Rüdersdorf.
2. From limestone nodules of the island of Sheppey.
3. From a triassic limestone, covering the strata of lead ore, near Tarnowitz.
4. From Hausbergen.
5. From Metz.
6. From Holkin Mountain, near Holywell Flintshire.

ORIGIN OF THE PORTLAND CEMENTS.

No. 1. English cement from White & Bro.
2. From Stettin.
3. From Wildau.
4. From Wildau.
5. Pomeranian Star cement.
6. From Stettin.
7. English cement.
8. From the Bonn Mining Company.
9. From Kraft & Sanlich, at Perlmoos.

MANUFACTURE OF PORTLAND CEMENT.

Suitable limestones and certain kinds of clays are selected, mixed intimately in certain proportions, and calcined at a high temperature. The carbonic acid gas separates from the lime at a moderate red heat. But the mixture for Portland cement has to be subjected to a higher heat, because the hydraulic properties of the cement increase, to a certain extent, with the temperature at which it is calcined. It ought to be softened by the heat, but not so much as to assume the dense structure of a melted mass. This is effected at a white heat. The clay is thereby completely decomposed through the action of the lime, and silicate and aluminate of lime are formed. The calcined mass contains, besides these two compounds, which are its principal constituents, smaller quantities of silicate of alcali, silicate and aluminate of magnesia, and, perhaps, some sulphate and phosphate of lime.

The calcined mass is ground fine, mixed with a little water and worked into a paste. Cement thus prepared hardens more and more, the longer it is exposed to water, or to atmospheric air. Good Portland cement gets as hard as fluor-spar, and equals the best limestones in solidity and durability.

SELECTING AND MIXING THE MATERIALS.

Any kind of carbonate of lime is fit to be used in the manufacture of Portland cement. Marble, limestone, chalk and marl may be used. Chalk and marl often include foreign matters, such as flints, feldspar, sand, which have to be removed by washing.

The clay used must be of a certain chemical composition, which can be seen from the following analyses of celebrated kinds:

	1.	2.	3.	4.	5.
Silicic acid	68.45	60.06	59.25	60.00	62.48
Alumina	11.64	17.79	23.12	22.22	20.00
Peroxide of iron	14.80	7.08	8.53	8.99	7.33
Lime	.75	9.92	.....	4.18	6.30
Magnesia	.....	1.89	2.80	1.60	1.16
Potassa	1.90	2.50	1.87	1.49	1.74
Soda	2.10	.73	1.60	.72	.37
Sulphate of lime	.....	.60	2.73	.89	.60

ORIGIN OF THE ABOVE CLAYS.

No. 1. The celebrated Medway clay.
2. From the Prussian Province of Saxony
3. From Pomerania.
4. From the Upper Hartz Mountains.
5. From the Province of Brandenburg.

It is to be seen from the above analyses that the clays most adapted for the manufacture of cement contain considerably more silicate of alumina than kaolin does. Lime and clay have to be mixed very intimately. If this condition is not fulfilled, a good cement can never be obtained. The most perfect method of doing this is to mix them when suspended in a large quantity of water. However, the success of the manufacture depends not only on a thorough mechanical mixing, but also on the proper chemical composition. A careful examination of a large number of good Portland cements has shown that the proportions of the three principal components ought to be within the limits indicated by the following two examples of composition:

I. 80 equivalents of Si O^2 (silicic acid).
210 " " Ca O. (lime).
27 " " Al^2O^3 (Fe^2O^3) (alumina and peroxyde of iron).

II. 30 equivalents of Si O^2 (silicic acid).
230 " " Ca O (lime).
15 " " Al^2O^3 (Fe^2O^3) (alumina and peroxide of iron).

Supposing the sesqui-oxydes to play the part of acids, these two compositions correspond to the formulæ:

$$\text{I. } 10\ Si\ O^2\ (R^2\ O^3) + 20\ Ca\ O$$

(10 equivalents of silicic acid and sesqui-oxydes, with 20 equivalents of lime).

$$\text{II. } 10\ Si\ O^2\ (R^2\ O^3) + 24\ Ca\ O$$

(10 equivalents of silicic acid and sesqui-oxydes, with 24 equivalents of lime), which represent the limits of the composition of good Portland cement, and are of great value in preparing the mixtures of lime and clay.

The following facts will give an idea of the hydraulic properties acquired by the single components of cement, when they are mixed with other components and calcined: Silicic acid and lime are the most important components of cement in quantity and quality. When mixed together and calcined they form a compound which hardens under water. Not only amorphous silicic acid produces this effect, but also crystalline quartz, when heated with lime to a white heat. Carbonic acid affects and decomposes silicates of lime. The artificial silicates resist this decomposition the better, the more compact and dense the silicic acid was, in its raw state. Silicic acid and alumina do not alone combine chemically in water at ordinary temperatures after being calcined together.

Lime and alumina have a considerable affinity for each other. When mixed and heated they combine, and form hydraulic compounds, which harden with water perfectly well, especially when they have been produced at a high temperature. When compounds of alumina with one, two or three molecules of lime are finely pulverized and mixed with a little water, they become binding at once and form hydrates, which get very hard under water. By mixing the aluminate 2 Ca O, Al^2 O^3 with 30, 60 and 80 per cent of sand, Frémy obtained a mass that assumed under water the hardness and firmness of the best stone.

Lime and peroxyde of iron form a compound when calcined together. This compound is, however, less hydraulic than the aluminate of lime.

Calcined magnesia alone hardens well with water. It also forms with silica good hydraulic compounds.

Silicates of alcali are also useful in the process of hardening.

Sulphate and phosphate of lime do not aid the hardening, and may be considered as noxious ingredients, when present in considerable quantity.

CALCINATION.

The mixture of raw materials, made according to the principles above developed, is formed into pieces of uniform size (bricks), which are dried in the air and calcined. The furnaces used for calcining are generally kilns from 40 to 50 ft. high, and from 7 to 12 feet wide. Three or four feet above the ground they contain a strong grate, consisting of single bars, which can be removed when the calcination is completed. The calcined and slightly glazed mass of bricks slides down by itself in cooling, and is then extracted. The kilns are charged with alternate layers of fuel and cement bricks. The regular shape of the bricks allows of charging the kiln in such a manner that the escape of the gases can take place uniformly, over the whole section of the furnace, to effect a calcination as uniform as possible. Coke is generally used as fuel, because it is purer than coal; the sulphur contained in the latter would give occasion to the formation of sulphate of lime. If, however, raw coal is used, the kilns must have such a construction that the fuel does not come in contact with the cement, and that only the gases produced by the combustion pass through the furnace. The annular ovens, recently patented by F. Hoffmann and A. Licht, are used with great success for calcining cement, as well as bricks, lime and pottery. In these ovens the cement also comes in contact with the fuel, but a much smaller quantity of the latter is required, and the greater part of the ashes is gathered in the charging tunnels and does not mix with the cement.

A proper temperature in calcining is a very important matter. Cement calcined at too high a heat looses entirely its property of binding. The proper intensity of heat has to be found out by experiments for every single mixture. The denser the raw materials are, the higher the heat required. Mixtures prepared from compact limestone or washed chalk require a higher temperature than those prepared with light and porous kinds of carbonate of lime. The higher the temperature required, the higher the kilns have to be constructed. The temperature varies easily to an observable extent in kilns not holding over 150 tons. But the limits within which the temperature may vary without injuring the product are pretty wide. The hydraulic quality of the cement increases with the intensity of heat used in calcining. However, this is only the case to a certain extent. When overheated, cement gets too compact, and its capacity of hardening then decreases. A white heat is the proper heat for the calcination of Portland cement. If it is heated higher, it begins to run, and is then unfit for use. The best method to judge about the temperature existing in the furnace is to take samples of the cement under treatment from time to time. As the color of the cement changes with the increase of heat, the samples taken from the furnace will show by their color and appearance how far the process is advanced, and make it possible to regulate the temperature properly. The following will explain this:

The limestone looses its carbonic acid at a low red heat. At the same time the lime begins to decompose the clay. When a good red heat is kept on for an hour the mass becomes yellowish-brown, and can then be dissolved in diluted hydrochloric acid, the larger grains of quartz excepted. The capacity of the mass for hardening is, however, small yet. It gets hot, when mixed with water, and falls to pieces, when exposed to the air, like ordinary lime. With the increasing temperature the mass gets darker brown, more resisting to atmospheric influence, more capable of hardening, less liable to develop heat when mixed with water; all of which proves that the lime combines, chemically, more and more with the silicate. When the temperature is increased to a white heat the mass becomes grey at first, then assumes a greenish tint, which gets more and more distinct with a further increase of temperature. Up to this stage in the process of calcination the cement improves in quality, its density, firmness and capacity of hardening being increased. If the intensity of the heat still further augments, the greenish-grey color of the mass is changed into a bluish grey; and this is the stage when the cement begins to deteriorate. The mass gets more and more compact and resembles basalt. At last it enters a state of complete fusion, when it shows the appearance of obsidian, or vitreous lava. It is desirable to obtain a uniform pumice-like mass, of a greenish-grey color. Well mixed and well calcined cement ought to "stand," that is to say, it ought not to fall to pieces in cooling. This occurs, however, with burnt bluish-grey cement; and, also, with carefully calcined cement, when the chemical composition is not the right one. The more lime there is in the mixture the safer can the cement be calcined at a high heat without fear of its falling to pieces afterwards. Mixtures containing too much clay fall to pieces after the calcination. An addition of lime or alkali will prevent it, provided the cement is not burnt. The finer the condition and the more intimately the clay and the lime have been mixed, the higher can be the amount of lime used. But when the mechanical mixing has been done without accuracy and care, a greater amount of lime will only make things worse. It then does not prevent disintegration of the calcined mass, and adds, besides, another evil, causing it to become hot and to rise in contact with water. The utmost care in mixing can, therefore, not be enough recommended; for no good result can be obtained without it, whatever the proportions of the mixed substances may be. Whoever does not pay sufficient attention to this point, and attributes bad results to other causes, is inevitably led into errors and confusion.

The question, how much lime can be used, is answered by the formulæ I and II, given above, which indicate the limits. If on 10 equivalents of acids (including the sesquioxydes) less than 20 equivalents of lime are used, the cement will fall to pieces; if more than 24 equivalents of lime are used on 10 equivalents of acids, the cement will get hot with water and will not harden as a solid mass. The more lime a cement contains, within these limits, the slower it hardens, but the firmer and the more solid is the hardened mass, and the more valuable is the cement.

PROCESS OF HARDENING.

Well calcined Portland cement, when mixed with water so as to form a thick paste, becomes binding more or less rapidly, depending on its composition and on the heat to which it has been exposed. It solidifies and hardens in the air as well as under water. When hardening in the air, the cement does not lose any of the substances contained in it. When it hardens under water, a part of its soluble components, especially the silicates of alkali, are dissolved and extracted. The hardening process proceeds quicker at first in the air than in water, because carbonate of lime is then formed beside the silicate. But this takes place on the surface only, to a depth of about one-eighth of an inch. The interior mass remains free from carbonic acid and hardens equally fast in air or water.

Carbonic acid gas, though at first assisting the hardening process, effects afterwards a decomposition of the cements if they are loose or porous. Ground cement is rapidly decomposed by carbonic acid. The durability of the cement is, therefore, dependent on its solidity and density. The quantity of water that has to be mixed with the cement to prepare it for use, is about one-half the weight of the cement. This quantity is sufficient under ordinary circumstances. But in a high temperature, or when exposed to sun-heat for a long while, or when in contact with quite dry bricks, the cement may lose so much water that it cannot harden properly. It is not necessary to keep cement walls wet till the cement has hardened; but it is important to wet the bricks thoroughly before being laid in cement.

Hardened Portland cement, which is free from carbonic acid, contains 14 to 16 per cent of water. It is generally composed of:

1). Basic silicate of lime of the formula:

$$5\ Ca\ O.\ 3\ Si\ O^2 + 5\ H\ O.$$

2). Aluminate of lime (and the corresponding compound of sesqui-oxyde of iron with lime) of the formula:

$$3\ Ca\ O.\ Al^2\ O^3\ (Fe^2\ O^3) + 3\ H\ O.$$

3). Hydrate of lime. Ca O. H O. S.

Bessemer Royalties.—The statement circulated here, that they have been, or will this year be reduced, on products for either home or foreign consumption, is officially denied by Mr. Bessemer.

BURNING COAL DUST.

From "Engineering."

Those who have carefully studied the ordinary methods of burning fuel in our steam boilers and furnaces are well aware of its numerous defects, and of the losses of heat attendant upon it. Thus, besides the losses from conduction and radiation, which will take place to a greater or lesser extent with any system of burning fuel, there are, under ordinary circumstances, the losses due to imperfect combustion, to unconsumed coal falling into the ashpit, and to the heat carried off by the waste gases escaping to the chimney, this latter loss being largely increased by the excess of air which it is found requisite to supply to the furnace beyond that required for chemical combustion alone. To avoid these losses, various plans have been devised, the most thoroughly successful in practice, as well as one of the most perfect in theory of those hitherto brought before the public, being Mr. C. W. Siemens' beautiful system of regenerative gas furnaces. As far as the results obtained are concerned, these furnaces have really left little or nothing to be desired; but they have the disadvantage of being of considerable first cost, and, therefore, although they have been very largely adopted, they have not come into such general use as their economical working would otherwise warrant.

Under these circumstances various attempts have naturally been made to approximate more or less closely to the economy of the regenerative gas furnace without at the same time involving so great an outlay for gas producers, regenerators, &c.; but—although several experimenters have obtained good results—until quite recently no plan which could be said to be a fair competitor of Mr. Siemens' system had, so far as we are aware, been brought forward. A few months ago, however, Mr. Thomas Russell Crampton commenced experimenting on methods of burning fuel in the form of powder, and the practical results which he has lately obtained are so striking that we are inclined to regard his system as one possessing very great importance from many points of view. And here we may remark that the plan of burning fuel in a powdered state is, in itself, not new. Both in this country and abroad—and particularly in America—many attempts have been made to burn coal in the form of dust or finely divided particles; but prior to Mr. Crampton's experiments these attempts met with but indifferent success. One great difficulty which troubled most of the experimenters was that the flues of the furnaces became clogged with dust, this dust consisting in a great measure of unconsumed fuel, and representing, therefore, so much waste, besides being a practical inconvenience which it was found impossible to avoid. Mr. Crampton, however, *has* avoided this inconvenience, and the arrangements he has employed to enable him to do this have at the same time enabled him to obtain other advantages, of which we shall speak in due course. In the first place, however, we must explain briefly the principles upon which Mr. Crampton's system is based—principles, we may remark, in which sound common sense occupies a conspicuous place.

If two jets, one of coal gas and one of atmospheric air, be introduced into a chamber side by side and a light applied, a long flame will, as everybody knows, be produced, the length of this flame increasing according as the pressure under which the jets of air and gas are delivered is increased. Even if the gas and air are mixed before being introduced in the chamber, and are delivered into the latter through a single jet, the flame will still be produced, the length, although less, being, as before, increased by an increase of the pressure under which the jet of mixed gas and air is delivered. Now the existence of this more or less elongated flame proves that the combustion of the gas, even when mixed with a supply of air, is far from being instantaneous, and that, in order that perfect combustion may be obtained, a certain time must be allowed to elapse before the mixed gases are brought into contact with the objects which would reduce their temperature below that at which chemical combination will take place. When the fuel is supplied in a solid instead of a gaseous form, a still longer time is necessary for the completion of the process of combustion, the larger the particles of fuel the longer being the time thus required.

It is a recognition of this fact, that *time* is required to complete combustion, that forms the basis of Mr. Crampton's system of buurning powdered fuel. Instead of projecting the coal dust into a chamber where the heat is to be utilized, he mixes it with the requisite supply of air, and delivers the mixture into a combustion chamber or flue of such length or provided with such baffling screens that time is afforded for the combustion to be completed, before the heated gases which are produced arrive at the point where the heat is utilized. The time requisite to attain this end may be obtained by forming the combustion chamber with a zigzag flue, or by placing across it perforated screens of brickwork, which will form baffles, and delay the current of gases. In any case, openings are provided for drawing off the slag, which is deposited in the combustion chamber.

Of course the smaller the particles in which the fuel is supplied the greater will be the surface exposed by them in proportion to their weight, and the shorter therefore will—as we have already stated—be the time required for their combustion. In other words, the finer the particles the more nearly will they approach in character to gaseous fuel, and therefore if it were not for certain commercial considerations it would be advisable to reduce the fuel to the finest particles possible. Although, however, coal may, by suitable mechanical contrivances, be readily reduced to a state of impalpable powder, such reduction would be expensive, and therefore from an economical point of view unadvisable. Mr. Crampton has given this matter careful consideration, and we believe that the conclusion he has come to is, that regarded from a commercial point of view, it is unadvisable to spend more than one shilling per ton on reducing the coal to powder; or, in other words, that the coal should be reduced to as small particles as is possible for this expenditure, but that the advantages to be gained by the use of finer particles would not compensate for the extra expense of producing them.

To reduce the coal to powder, Mr. Crampton proposes to use ordinary millstones having a blast of air passed between their grinding surfaces, this blast both keeping the stones cool and carrying off the fine particles as soon as they are produced. The coal may, of course, if desired, be crushed between rollers, or by other means, before being fed to the millstones. The methods of delivering the mixture of powdered fuel and air into the combustion chamber, employed by Mr. Crampton, vary somewhat according to circumstances; the plan, however, which appears to be most generally applicable is that in which the powdered fuel is delivered from a hopper by means of a feed-roller into a coned pipe or nozzle, within which is a smaller nozzle discharging air under pressure. A kind of injector is thus formed which delivers the mixed air and powdered fuel into the main pipe leading to the combustion chamber, this pipe being traversed by a current of air under a low pressure. In this arrangement the feed-roller can receive its motion from a little engine directly attached to it, this engine being driven by the compressed air supplied to the injector nozzle. Where the furnaces are distributed about the works, the employment of little independent engines in this way will be a great convenience, and will save the erection of shafting.

We have said that the experiments already made by Mr. Crampton on his system have given most satisfactory results, and we hope to be able in an early number to lay the full details of these results before our readers. In the meantime, however, we may point out some of the advantages which Mr. Crampton's system appears to us to possess. In the first place, besides enabling ordinary good small coal or slack to be efficiently consumed, it affords great facilities for burning coal of inferior qualities. Take, for instance, coal containing a large proportion of sulphur. In order that such coal may be utilized for metallurgical operations in ordinary furnaces, it is requisite that after being powdered and subjected to a washing process, it should be moulded by pressure, &c., into blocks, while by burning it in the powdered state all the moulding process would be dispensed with. In cases when the coal merely contains an admixture of earthy matters, unaccompanied by deleterious volatile ingredients, the advantages in favor of Mr. Crampton's system are still greater. In such cases it is not even requisite that the coal should be washed, it being merely necessary to reduce it to powder, the presence of the earthy matters merely increasing the quantity of slag deposited in the combustion chamber without interfering with the perfection of the combustion. In dealing with the poor coals of India and similar fuel this would be an important consideration. Another advantage consists in the saving of labor effected, the supply of the powdered fuel to the furnace being regulated merely by opening or closing a valve, while there is the further advantage that the supply of air needed is little if any greater than that required for chemical combination, so that the intensity of the heat attainable is far greater than in an ordinary furnace where there is necessarily a surplus of air present. As a result, moreover, of the nicety with which the supply of air can be adjusted, the formation of smoke can, as the trials have shown, be completely avoided. Again, the system offers great facilities for utilizing the heat which would otherwise be carried off by the waste gases, it being merely necessary to pass these gases through regenerators arranged on Mr. Siemens' plan, and employ these regenerators to heat the air which is mixed with the coal dust in the first instance. In reheating and other similar furnaces, also, the fact of a slight pressure being maintained within the furnace is an undoubted advantage, as it prevents the indraught of cold air through crevices, or when the furnace doors are opened. Altogether, we consider that Mr. Crampton's system of burning powdered coal fuel is one which is well worthy the attention of all interested in the economy of fuel, and we anticipate that it will come into extensive use. We shall have more to say about the system in a future number, when we shall be at liberty to publish details of the trials, which have already been made on a practical scale.

CULVERTS UNDER RIVERS AND CANALS.

From the "Mechanics' Magazine."

There is always more or less hazard and risk in disturbing what may be called the "existing state of things." Nevertheless, it becomes imperatively necessary, on certain occasions, to incur the risk of so doing. Of all the examples of engineering practice, in which a corroboration of this statement is to be found, that relating to interfering with the *status quo* of the beds and banks of rivers and canals, affords the most conclusive one. Numerous have been the accidents, and dire the consequences of excavating even in the approximate locality of these situations. It is impossible to observe too much caution in conducting operations of this nature, which have now become more frequent than formerly. This is partly owing to the fact that rivers are no longer regarded as inseparable barriers between their opposite shores, and that attention has, during the last few years, been prominently drawn to the practicability of effecting a communication underneath instead of overhead. This has been exemplified on a gigantic scale by the proposed submarine communication between England and France, and is being practically carried out by the Waterloo and Whitehall Pneumatic Company, and by the construction of the subway under the Thames at the Tower. Although not arrived at this pitch of subfluvial tunneling, the French have accomplished something in that line, by the large syphon tube recently successfully laid under the Seine, to connect the sewage channels on each side of that river. The laying of culverts and pipes under embankments has always been a source of anxiety and trouble to the engineer, even when the embankments are made at the same time. It is needless to point out how greatly the trouble increases, and how much greater need there is of precautionary measures, when the case involves the undermining of a bank already *in situ*.

There are two very prominent instances to be adduced where the laying of pipes and culverts underneath the banks of water reservoirs were attended with leakage and bursting. The one is the well known catastrophe at Bradfield, some few years ago. The other is the leakage and subsequent emptying of the Vartry reservoir, constituting a portion of the Dublin Water Works. Whatever might have been the true cause of the former mishap, whether it was due to an error in the principle of construction adopted, or in practical working defects, there is very little doubt about the latter. The extrados of the arch of the culvert was left nearly smooth, without any offsets, steps, or "racking back," to afford a firm hold of the puddle of the bank. In fact, there was really a straight joint between the puddle and the masonry, whereas there should have been a union as intimate as it was possible for ingenuity to imagine. As might be expected, the water found out the "weak spot." The result was the emptying of the reservoir, which had taken months to fill, and the plunging of the Dublin Corporation into litigation, which entailed upon it a large amount of expense. In many of the towns where new sewage works are in course of construction, it has been necessary to lay iron pipes below the beds of the adjoining rivers and canals, both for the purpose of effecting a communication between the sewers upon the opposite sides, and also, in some instances, to constitute a channel of conveyance for the sewage to the fields intended to be irrigated. This subaqueous plan has been adopted at Norwich, where very extensive drainage and sewage works are in progress. Some idea of their extent may be gained from the fact that they are estimated to cost £60,000. Provided the foundation be good, and concrete be used liberally, the only point presenting much difficulty is the joints, which sometimes give a great deal of trouble. The depth to which the drains must be sunk depend, in the first place, upon the levels; and, secondly, upon the condition of traffic in which the river is placed. If the river be navigable, and used for the purposes of navigation, the pipes should not be placed too near the surface, and should be well protected, especially about the joints, with cement concrete, or they are liable to be damaged by the anchors of boats. Were there any choice in the matter, it would always be preferable to take the drain or pipe over instead of under the river, but it is seldom that the levels are so entirely optional as to afford the right of selection.

An instance of the bursting of a canal embankment, in consequence of excavating underneath it, for the purpose of constructing a culvert, occurred a very short time ago. A portion of the embankment of the Napton and Warwick Canal was washed away, making a breach nearly 40 ft. in width.

As a rule, we should prefer in these hazardous situations to lay cast-iron pipes instead of building a culvert. The time which the disturbance and interference with the existing bank occupies is of equal importance with the nature of the operations carried on. A much shorter time will suffice to lay in a pipe than to construct a culvert of brickwork or masonry. The former will also require less excavation than the latter, for supposing them to have the same internal dimensions, the arch, invert, and side walls of the culvert, will necessitate the taking out of considerable additional quantity of earth. These proportions in a cast-iron pipe are simply its thickness, which practically is inappreciable. Besides, an increase in the capacity or internal size of the pipe, produces little or no corresponding difference in the thickness. With the exception of the difficulty sometimes experienced in making good the joints, there is no comparison with respect to the relative facilities of the two methods for establishing a speedy and secure communication between the opposite banks. The manner in which the canal is constructed, at the place where the intended pipe or culvert is to cross, has a very great effect upon the risk attending its successful laying. Should the canal be carried altogether in an embankment, and the levels not permit of the pipe being laid in the natural ground, but require it to be placed in the artificial bank, the danger is seriously augmented. Not only is the foundation more treacherous and insecure, but the earth above is more liable to subside than if it consisted of a thin stratum of the natural surface. Subsidence is not necessarily a forerunner of leakage or bursting, but it frequently does precede these serious contingencies, and may be regarded as a warning sign which should never be disregarded. A distinction must be drawn here between the ordinary subsidence, which invariably follows the erection of every new bank, a short time after its construction, and that for which there is no apparent cause. The former is always expected, and provision made accordingly for raising the bank to its proper level. The latter should be at once carefully inquired into, and a constant watch set on the spot.

IRON AND STEEL NOTES.

Duration of Blasts.—A metallurgist who has spent the past winter in traveling among the French and English furnaces, gives it as his opinion that many of the recently-constructed and systematically managed establishments of the United States have nothing to fear from a comparison with the very best in Europe. In fact, there are some respects in which the ironmasters of this country are decidedly in advance of their trans-Atlantic compeers. The ever-increasing consciousness of the necessity of very high temperature in the blast is far more generally acknowledged and obeyed in this country than in Europe; and the average number of workmen required to perform the usual labor about the furnace is much greater there than here.

This observer gives the palm, among the works which he visited, to the furnace near Middleboro', in the Cleveland district. "Everything," says he, "is new, practical and neat, even to elegance."—Whether, however, in the colossal furnaces of that neighborhood the limits of economy have not been passed, is a serious question. The two furnaces at Rosedale are 103 feet high and 27 feet in the boshes. Certainly their production of eighty or ninety tons per twenty-four hours, great as it is, seems to be below the proportion of their vast dimensions.—Probably the use of the Lürman cinder-block, which has been adopted at some of the works, will be found especially advantageous in raising the product of very large furnaces, since it brings the slag discharged much nearer the center of heat, to say nothing of other favorable effects.

One point of difference between American and foreign blast furnaces is not in our favor. We are not able to keep as long in blast as do the Europeans. This complaint is quite general among us, and it is well worth while to inquire whether the difficulty arises from a defect in the quality of our natural or manufactured fire-proof material. With a view to answer this question, careful experiments have been made abroad upon samples of American clay and bricks furnished by W. M. Lyon, Esq., of Pittsburgh, and the results have just been communicated to us by Mr. George Asmers, under whose direction they were instituted.

It was found that our Mount Savage fire brick excels the best varieties in Scotland, Germany or Belgium, and that our Star at least equals them.—A third brand of cheap American brick, the Porter, showed itself not sufficiently fire-proof to be used even in the upper parts of blast-furnaces. These experiments do not by any means prove that there are not many other kinds of American fire-brick as good as those mentioned. In fact, we have ourselves obtained and manufactured material from New Jersey which successfully resisted tests before which the famous Stourbridge brick gave way.—The question to be answered in these experiments was merely whether it would pay to import Scotch or German brick on the assumption that all American material is defective. This question is now clearly answered in the negative; and if Mount Savage or Star bricks do not hold out as long as Garnkerk, the reasons must be sought elsewhere than in the raw material. Most complaints of this kind come from furnaces which smelt the very rich ores of Lake Superior, and that, too, with extremely small additions of lime. Under these circumstances, the formation of cinder at the expense of the alumina of the fire-brick is inevitable. The evil is aggravated when the blast is not so strong; as, for instance, at the charcoal furnaces of Lake Superior, when the pressure is but one and a half pounds. The zone of fusion here becomes annular, and hugs the walls, producing such a rapid action upon them that it is not surprising that the blasts in that neighborhood seldom last longer than twelve or fifteen months.

Careful experiments only can determine whether it would be wise to change the present proportion of flux and the pressure of blast to gain the advantage of longer campaigns. Such question cannot be flippantly answered *a priori*. One thing, however, is now certain. We do not need to look for better material in the construction of furnaces than our own country affords.

[The above is from the "Journal of Mining."—The "American Exchange and Review" makes the following comments :]

In addition to the above, it may be said that there is as singular a variation in the endurance of English furnaces as there is in furnaces in this country, in districts where the ores vary. We speak now in respect of the endurance of the furnace ring or inner walls. The gentleman last named is upon the line leading directly to the cause of difference between the endurance of American and of European furnaces. The peculiarity of ores demands a peculiarity in fluxing, and if that type or normal condition is not reached in the charge thrown into the furnace, the silex and alumina, not the alumina alone, must suffer, and the brick is dissolved or fluxed in itself. The nature of the ores reduced, therefore, has much to do in bringing about the difference in endurance. This may be considered a probable suggestion when we notice the large amount of lime in the charges of English furnaces as given in the type cinder of Dr. Percy, namely, 38 silex, 15 alumina, 47 lime; whereas in the large majority of our American furnaces 30 of lime would be the maximum.

Experiments at the Joint Expense of Ironmasters.—The Staffordshire correspondent of "The Engineer," says : Amongst some of the most advanced producers of pig and finished iron in this district, there has for some time been a desire that such a combination should exist that experimental works may be carried on at the cost of a joint purse and for the benefit of all, such as machine puddling, and other suggested improvements in the mill and forge department.

The same idea is now finding expression in respect of the making of pig iron. A South Staffordshire ironmaster, who within the last six years has made five visits to the Cleveland district, bases upon what is being done there an appeal to the trade in his district, to devise some machinery by which they may at one cost try each separate experiment, and to learn what would prove most valuable for permanent adoption. "During my first visit, I saw (he says) furnaces in advance of any then in Staffordshire ; since then, at some of the works, those furnaces have been altered once or twice, and are now either rebuilt, or are about to be." Indeed one of the Cleveland ironmasters himself remarked to me, in consequence of my having said that I had thought, the first time I was in the district, that the furnaces were so perfect they would probably remain for years unaltered : "In the last six years I have built five furnaces, each in advance of the other ; I have now pulled them all down and rebuilt, or am about to rebuild them as 85 ft. furnaces, with 27 ft. boshes, capable of making 450 tons of iron per week."

The South Staffordshire master remarks : "This seems a very lavish way of laying out money, but let us examine it more closely. To rebuild a furnace would probably cost somewhere about £1,000, but if by rebuilding you can save 1s. per ton on say 200 tons per week it would amount to £520 saved per year, or upwards of 50 per cent on the outlay." Now, as their furnaces make up to 450 tons per week, it is evident that they are wise to alter where they can see a saving of anything like 1s. per ton. What we want is a system of trying every new plan on one given furnace, and under the same circumstances, and in such a way as to obtain perfectly reliable data, such data to be open to all subscribers. This could be best done by forming a Blast-Furnace Institute, each member subscribing so much per furnace, according to the number of furnaces that he owned or leased. Such an institute would have a working committee, who would build or engage one or more furnaces, as well as a manager, and keep all accounts on the cost-book system, showing each separate account. The committee should meet at least once a month, and individually make frequent visits to the trial furnace. Say they are working a 50 ft. furnace, and at the first meeting agree to try the proper working height of furnaces with the different coals of the district. The furnace would be burthened to its very outside working powers at that height, with each of the coals to be tried, strict returns of the yields of everything being kept. These being finished, let the furnace be raised 5 ft., and then try them all again. Should any or all of them prove to work to better advantage at the increased height, then raise another 5 ft., and go on in the same way till that experiment was exhausted. We might then try increased heat of blast, or a close hearth, and then the yield of any one or all ironstones by themselves. The value of such an institute no one can tell, but supposing that by trying heights we saved as much as five cwt. of coal to the ton of iron—in Shropshire they save seven cwt., and in Cleveland upwards of ten cwt.—it would be somewhere near equal to adding one-seventh to the life of Staffordshire, whilst it would improve the quality also.

New Blast Engine. — A blast-furnace engine built at Norwalk, Conn., and described in the the "American Exchange and Review," has the following peculiarities: It is a vertical engine.—The air cylinder is 72-in. diameter and 8-feet stroke; the steam cylinder 36-in. diameter. The air piston and follower, instead of being cast iron and having packing between, consist of a ring six inches in thickness, with space for packing, which will be of solid wool felted and set out by a spring ring. Instead of the one piston rod taking the piston in the center, there will be three taking hold of the outside of the air piston, passing up through the head *outside of the steam cylinder*, and fastened to the crosshead. The great advantage of this is that it entirely prevents any steam or water from being carried down the piston rod through the stuffing box into the air cylinder. The air piston being simply a ring held by the three rods, and the entire center being covered with boiler iron slightly concaved, is very light. The steam piston is cushioned at both ends by passing and closing the exhaust ports just before the termination of the stroke, thus rendering striking the heads absolutely impossible, besides making the change of stroke almost instantaneous, and in consequence of this the variation of the blast is little or nothing.

The Large Blast-Furnace at Norton, England.—We have received, says the "American Exchange and Review," the following description of the blast-furnace at Norton, near Stockton-on-Tees, England, erected by John Player, of Player & Henderson, 30 Broadway, New York. It is 85 feet high, and 25 feet across the boshes; cubic contents 26,000 feet; and closed top, or bell and hopper arrangement for charging; has one horizontal blast engine, blowing cylinder seven feet diameter by seven feet stroke, working twenty-two revolutions per minute; has four of Player's patent hot-blast stoves, of thirty pipes each: heating the blast 1,000° to 1,200° Fahr., pressure of three and a half to four and a half pounds on the square inch, using six *tuyères*. It was blown in March, 1867, and in 1868 produced 25,327 tons of pig iron; and in February, 1869, was producing about 600 tons of foundry iron per week. The consumption of fuel is about one ton to the ton of pig iron. The ores are now 42 per cent, yielding two per cent better than with smaller furnaces. Less goes into the slag, or cinder, than formerly with the small furnaces. The fuel is ordinary coke that could not be worked in small furnaces, owing to its injurious effect on the quality of the iron.

The gas arrangements, or rather the arrangements for drawing it off, are so perfectly constructed that the supply is divided up into sixteen different jets, or flues, so that each stove and boiler has its supply independent of the other, and there is enough for steam and for heating the blast; it is regulated and consumed with the same facility that ordinary lighting gas is consumed in a dwelling, and is consumed on the principle embraced in an Argand burner, by a gas regulator.

The production of this furnace has exceeded the anticipations of the parties concerned by fully fifty per cent. It is illustrated in "Engineering" (August 10, 1866, p. 104), where it is stated that it was expected to produce 400 tons per week, while it now produces about 600 tons. It is expected that it will keep in blast five to six years longer, or seven to nine years in all. Owing to the time that it will probably remain in blast, the expenses of repairs will be less than in any other furnace, per ton of iron. There are no repairs to be charged to the hot-blast stoves, nor will there be, as, owing to the principles of their construction, none can be required. The labor account of this furnace is but a trifle in excess of that of one of eighteen feet, whilst the product is double.

Estimate of cost of this furnace at present wages and prices of materials, to include furnace, casting house, engine house, lift stoves, etc., complete to take the blast:

Foundations,	$5,300
Common bricklayers' work,	24,800
Fire bricklayers' work,	37,500
Cast-iron work,	25,000
Blast engine,	13,000
Boilers, etc.,	6,500
Pumps,	2,500
Machinery for hoisting,	3,500
Sheet-iron work,	4,000
Wrought-iron bands,	3,000
Valves, pipes, cocks, stays, etc.,	5,500
Various expenses, such as fitting, setting engines, boilers, scaffolding, extra labor,	15,000
	$145,600

We would modify this communication from Mr. Henderson by simply stating that we are under the impression that his estimates of cost of producing iron on the Lehigh are too low as to coal, limestone, and in some places in ore. The cost of limestone is about $1.75 in some places, of coal more than twice as much, even before the strike, and ore (brown hematite) is generally from $5 to $5.20 at the mines, to say nothing of the magnetic ore which forms nearly, and in some places quite, one-quarter of the charge, and is much more expensive. With what has been said in a previous article in the present number of the "Exchange and Review," our readers can draw their inferences as to the comparative excellence of small and large furnaces.

Mixing Iron Ores and Charges.—Dr. Crookes, in his new work upon iron, just received, has the following concerning the mixing of ores and charges:

1. Rich ores without earthy substances. They are mixed either with poor ores or with fluxes of blast-furnace slags, neutral silicates, etc.

2. Silicious ores. These are the most common; they are mixed with different fluxes, according to the state in which the silica is associated with the the ore, viz:

a. Silica is mechanically admixed with the ore, ores generally difficult to fuse, requiring aluminous and calcareous fluxes; best in the form of aluminous lime if suitable iron ores are not obtainable.—

Fluor spar has some advantages over common lime, as its fluorine volatilizes part of the silicon. It fuses easily with heavy spar, gypsum, and phosphate of lime, and is therefore a good flux for ores containing those substances. Ores at the same time containing quartz in a finely disseminated state and protoxide of iron are difficult to smelt. The silicious ores without manganese produce gray or mottled iron.

b. The silica is more or less saturated by other bases than iron. The silica is sometimes saturated with bases in such a manner as forms a suitable slag without the addition of other fluxes; or when contained in richer ores, an addition of neutral fluxes is required only to produce the sufficient quantity of slag. In most cases, however, the silica is not sufficiently saturated, and it then requires an addition of basic minerals, calcareous ores, or lime. In rare cases ores are smelted containing silicates so basic as to require an addition of silica or aluminous marl, etc.

c. The silica is combined with peroxide or protoxide of iron, as in puddling, refinery slags, etc.—These substances are difficult to smelt, and the best method is Lang & Frey's, according to which 25 parts of well burned fresh lime are slaked, and mixed while warm with 65 parts of pulverized slag and 10 parts of pulverized coal. The mixture is molded into forms, dried, and broken up to the size usual for smelting.

3. Calcareous iron ores being very refractory when smelted by themselves, are mixed with argillaceous iron ores or clayey substances. Pure quartz is seldom employed as an addition, for it requires a longer time for the formation of silicates, and is liable to scorify protoxide of iron.

4. Iron ores containing magnesia are very refractory, and require an addition of argillaceous substances and lime. If these ores contain at the same time a certain amount of manganese, the reaction of the magnesia will be partly neutralized.

5. Manganiferous iron ores sometimes smelt by themselves and are inclined to yield white pig iron, but they usually require an addition of lime in order to produce a slag free from iron. An increased addition of lime or magnesiferous substances is required if the production of gray iron is intended from these easily-fusible ores. Easily-fusible ores poor in manganese, such as some sorts of black-band, also require a greater addition of calcareous fluxes.

6. Titaniferous iron ores, usually difficult to fuse, require fluxes of lime and quartz. Alkaline fluxes are also very effective.

PLATING STEEL, ETC., WITH NICKEL.—There were recently exhibited before the Polytechnic Association of the American Institute, several specimens of iron and steel, upon which nickel had been deposited by the battery by a process devised by Dr. Isaac Adams, of Boston. It was claimed for this process, that while nickel is a much cheaper metal than silver, it is much harder, and is not affected by atmospheric influences, while at the same time the color is nearly equal to that of silver. Nickel is admirably adapted to the engraver's purposes, as from its extreme hardness, a plate of nickel will outwear several plates of copper. Hitherto it has been found impossible to deposit nickel to a greater thickness than that of a mere film. The mere deposition of nickel on steel is nothing new. Directions for the process will be found in Smee's work, published many years ago. But thus far it has been found impossible to deposit nickel in thick plates, for as soon as a film has been thrown down, the nickel is deposited in the form known as the "black deposit," which is friable and worthless.—Hitherto it has been thought necessary to use pure nickel for the pole or anode that is to be dissolved, but Dr. Adams has succeeded, even when the metal employed did not contain more than 75 per cent of nickel. Mr. Smith did not describe the process employed, as he stated that he was afraid his memory was not to be trusted in regard to it. The solution employed is the double sulphate of nickel and ammonia, but it must be prepared in a special manner, in order to insure success.

THE CLOSED HEARTH IN BLAST-FURNACES.—The correspondence of the "Engineer" thus mentions the use of this improvement in Cleveland:—The devices of the Cleveland iron-masters to stop all leakages or droppings, and to husband and economize all available products, are notorious. Nor are the other districts, so far as it is possible in the localities of old date, supine. The closed hearth system of working blast-furnaces, which has been applied to some forty furnaces in Prussia, is now being tried, we see, in Shropshire. By this system the hearth is kept much hotter than by the usual method, for there is no waste of heat to keep up the temperature in the useless channel between the hearth and the dam. Instead of blowing into the cinder, as in most of the English furnaces, the *tuyères*, upon Lürman's patent, are inserted on a level of about nine inches above the scoria outlet, thus bringing the full force of the blast upon the materials. Fuel is saved, and more iron, and of a better quality, is produced. The casting may be carried on without the blast being taken off, which is another source of economy, and the "blowing through" process after every cast, with its consequent waste of heat, is unnecessary. There is reason to conclude that the furnaces will not display a tendency to "bridge up," that condition of things being prevented by the intense heat, by which everything becomes thoroughly melted. So far as the experiments have already gone, the patent can be applied where tender as well as strong fuel is used.

THE SIEMENS-MARTIN PROCESS IN ENGLAND.—The North Yorkshire Steel and Iron Company, amongst whom Mr. Bernard Samuelson, the member for Banbury, is a conspicuous proprietor, have attempted to carry out the Siemens (Martin's) process for the manufacture of steel; but after much experimenting have, in reference, certainly, to some of the stages, abandoned the project, to the consequent great regret not alone of themselves, but likewise of the people of Newport, where numerous work-people began to find employment in a new avocation, but are now being discharged. The attempt is not, however, to be definitely given up. —*Cor. Engineer.*

NEW HEATON PATENT.—The invention of Mr. John Heaton, of Langley Mills, Derby, just specified, relates to improvements in the manufacture and production of iron and steel, and consists in the employment of the cinder or slag resulting from the balling of steel or of steely iron which has been obtained by the action of nitrate of soda or of nitrate of potash upon cast-iron, either in a converting vessel or apparatus such as is described in the specifications of letters patent granted to him (Nos. 798 and 1,295), or in any other suitable furnace or apparatus. This cinder or slag he employs either in what is known as the puddling process for the production of malleable iron, or of steel from cast-iron, or in the blast-furnace, for the purpose of improving the quality of cast or pig iron to be produced. In the employment of the product obtained by heating together oxide of iron and carbonate of soda, er caustic soda, or mixtures of the same for the production of malleable iron or steel from cast-iron, in what is known as the puddling process, and also its employment in the blast-furnace, for the purpose of improving the quality of cast or pig-iron to be produced.

PUNCHED STEEL AND IRON TUBES.—It is upwards of two years since we first publicly drew attention to the interesting process of making tubes by punching a solid ingot, and gradually enlarging it afterwards by punches of successively increasing diameter, so as to put the work upon the tube from the inside instead of, as heretofore, longitudinally. Messrs. Deaken & Johnson's punched tubes have since achieved a great commercial success. Upwards of a quarter of a millton have been made, and in many large contracts abroad, especially for the Remington rifles, no others are used.—*Engineering.*

TESTING MACHINE.—A writer in "Engineering," remarks that in some tests which he witnessed with the Kirkaldy machine, a trammel used on the bar itself, showed a far less amount of extension under various strains, than was indicated by elaborate machinery and index attached to the instrument for this purpose. This is an important point to have in view in connection with such tests.

THE pig-iron product of Great Britain in 1868 was 4,800,000 tons, that of the United States 1,603,000 tons.

ORDNANCE AND NAVAL NOTES.

EUROPEAN SMALL ARMS.—With regard to small arms, the most prominent feature of the year has been a continuation of the activity to which the events of 1866 gave the first impulse. In the North German army, the work of arming the troops with the well-tried needle-gun was pushed vigorously forward. For the fortresses, rifled percussion-guns of home and foreign construction (Austrian, &c., taken in war) were transformed into breech-loaders. It is proved, by the result of trials made at the military practice school in Spandau, with guns of the most approved systems, that the needle-gun, in precision and rapidity of fire, is inferior to none. On the other hand, the superiority of the small caliber, under some circumstances, is a matter that merits serious consideration. Hesse, Baden and Wurtemberg have armed their contingents with the needle-gun. Bavaria will not remain satisfied with the Podewils gun transformed on Lindner's system, and will probably adopt that of Werder. Austria has not yet completed the transformation of her old rifles according to the system of Wanzl. The model of Werndl presented some difficulties of construction, but the manufacture is now said to be going orwards. Here, as everywhere, it is the metal cartridge that has caused the trouble. Since April, the French infantry have been armed with Chassepots; but this is only the case with the army on its peace footing. Although private industry abroad and at home has been had in requisition, a sufficient number of these arms has not been procured for the army when in war, not to mention the reserves. Liège supplied 40,000 last year, and hopes to finish 80,000 in 1869. In spite of some defects, which the Minister of War himself acknowledges, the weapon seems, on the whole, to give satisfaction.

For the National Guard, the old rifles are being altered according to Snider. Italy and Russia have adopted the needle-gun. The Italian rifle pretty closely resembles the Dorsch and Baumgarten construction. In Russia the change progresses very slowly, and the breech-loaders, altered after the model of Carlé, are, according to the latest news, only in the hands of the guard. Berdan is contemplated as a new model, and of these 50,000 are said to be in readiness. Only the North German Confederation, with Baden and Wurtemburg, is at present completely supplied with breech-loaders, and then come France aud England. All the other States are more or less behindhand in this respect. At present the needle-system preponderates, as four great States and several of the smaller have adopted it.—*Kreutz Zeitung.*

THE MONITOR SYSTEM GAINING GROUND.—A British captain recently said: "For nineteen years we had to deal with vessels which we knew were worthless to fight in. They were gorgeous in appearance, rich in tradition, associated in the past with all our naval glories, and it is a bitter thing to part with them; but, still, that old wooden fleet has been at last got rid of, for last night the First Lord of the Admiralty promised you that even your reserve in future should be an irou-clad fleet. Having got rid of that wooden fleet you have now to prepare yourselves in the next ten years, if you are governed and led as you should be, to find the fleet trusting to steam machinery alone for its progress."

Whereupon the "Army and Navy Gazette" remarks: "Until Americans and French, Prussians and Russians decide upon ceasing to build iron-clads, casting and building up 20-ton guns, rifling and smooth-boring and manufacturing other implements for the ready and wholesale destruction of human life, we cannot afford to be behindhand; and so we fear the ugly, low, iron floating citadels must drive from the face of the waters the stately three-decker. War is a business, sad as it may be, and those who engage in it cannot indulge in a sentiment which might lead to bankruptcy. We must make up our minds to fight when called upon behind twelve or fifteen inches of iron armor-plates, and our movements regulated by steam power representing the combined strength of nine or ten thousand horses."

When the British navy comes down from three-deckers to "ugly, low citadels," protected by twelve or fifteen inches of iron," and propelled by "steam machinery alone," it will be a splendid realization of the *American idea*, first proposed by Stevens and made practical by Ericsson.

COMPARATIVE EFFICIENCY OF THE NEW BRITISH GUN.—A 9-in. Frazer gun, made for an endurance trial—a trial *à l'outrance*—has withstood upwards of 1,100 discharges, and of these 400 were full service rounds of 30 lbs., with 250 lbs. rifled shot, while the remainder were battering charges of 43 lbs., with the same shot. The gun is scarcely enlarged in the chamber, the rifling hardly worn.—It is a reason for just national pride, or, rather, for an even greater pride. No Krupp gun of large bore could be adopted with confidence in our naval service. No French gun could hold its own for an hour against such a test. As for the American guns—the huge smooth bores—they have been officially condemned and abandoned by the ordnance engineers of the cousin country.—*Engineering.*

We are greatly indebted to cousin Bull for working out the Fraser gun—at a fabulous cost. When it is quite perfected we shall adopt it in places to which it is suited. Meanwhile we are equally thankful to cousin Bull for disbelieving in the Rodman XV inch. It answers very well our modest requirements—such as enduring the thousand test rounds, firing hundred pound charges, and smashing such targets as it has been aimed at. The late Congressional ordnance committee, referred to by our cotemporary as the "ordnance engineers" of America, have, indeed, abandoned the Rodman, but as long as it is retained and believed in by the army and navy it will meet our wants till the Fraser and the Woolwich machinery are so far perfected that they can be safely copied.

French Merchant Marine.—The following results relating to the mercantile marine of France are taken from the general table of the foreign commerce of France just published by the Minister of Agriculture, Commerce, etc. On the 31st December, 1867, the total tonnage was 1,042,751, and at present is 1,048,679, showing an increase of 5,,928 tons. The number of vessels is 15,602. Of these, 7,212 are below 10 tons ; 4,757 from 10 to 100 ; 2,733 from 100 to 300 ; whilst above 800 there are only 76. Out of that total 215 are steamers representing 86,102 tons, an augmentation being found over the previous year of 8 ships and 11,192 tons. These figures are of great interest, as they show the constant advance of constructions intended to accelerate navigation. The port of Marseilles has the largest share—viz., 172,829 tons distributed amongst 792 vessels. Havre comes next with 132,296 and 390 ; Bordeaux, 129,167 and 413 ; Nantes, 114,734 and 647. Bordeaux has the greatest number of large vessels—283, from 100 to 800 tons. The difference between the entry and departure in ballast is considerable. In 1867 the tonnage was 19,000 for the former and 2,505,000 for the latter. The figures for loaded vessels are 6,366,000 and 4,125,000 respectively. The result is that France has always great difficulty in finding export freights.—*Army and Navy Gazette.*

Construction of Armor Plate.—Two armor plates, each 5 in. thick, manufactured by Cammell & Co., for the Austrian government, were recently tested by four shots from the 8-in. smooth bore at 30 ft. range. The one plate was made in the ordinary way, the other was made up of three thicknesses, by placing an armor plate $4\frac{1}{2}$ in. thick between two thinner plates, and rolling them down to the required thickness of 5 in. It was remarkable to see how closely the one plate resembled the other after the tests had been made, the greatest indents being 2.5 in. and 2.4 in. respectively, while the bulge in the back in both instances were $3\frac{3}{8}$ in. over an area of 2 ft. 3 in. and 2 ft. 4 in. respectively. It was clearly established that there was practically no difference in the merits of either plate. and both will receive a high classification.

The above is from an engineering and metallurgical journal of high authority, which fact prompts us to ask if all rolled armor plates are not made from piles of thinner plates, rolled down to the required thickness. We should think a difference rather than a resemblance in the results mentioned —the iron being the same—would have been remarkable.

The Russian Fleet.—The following are the particulars of the Russian fleet, as given in the "Journal of St. Petersburgh," from the report of the Ministry of the Marine : On the 1st of January, 1869, the fleet counted 230 steamers and 37 sailing vessels. The former consisted of the following armor-plated vessels : 4 frigates, 3 batteries and 13 monitors. Non-plated vessels : 6 ships of the line, 8 frigates, 18 corvettes, 7 clippers, 62 gunboats, 6 vessels colled "vapeurs-frigates," 4 imperial yachts, 13 schooners, 22 transports, 48 despatch boats, and 16 chaloupes. The sailing vessels consisted of 5 yachts, 4 schooners, 15 transports and 13 chaloupes. Of these 156 vessels were in the Baltic, 1 in the White Sea, 30 in the Caspian, 41 in the Black Sea, 31 on the eastern coasts of Siberia, and 22 in the sea of Ural. There were, in addition, 4 plated frigates and a steam yacht on the stocks in the Baltic, and 2 gunboats on the Siberian coast.

Bridge Building in War Time.—Bridge building was one of the arts brought to the greatest state of perfection during the rebellion. General McCallum states that the Rappahannock River bridge, 625 feet long and 35 feet high, was rebuilt in nineteen working hours; Potomac Creek bridge, 414 feet long and 82 feet high, in forty working hours; Chattahoochee bridge, 780 feet long and 92 feet high, in four and a half days; that between Tunnel Hill and Resaca, 25 miles of permanent way, and 230 feet of bridges, were constructed in seven and a half days; and near Big Shanty, $35\frac{1}{2}$ miles of permanent way, and 455 feet of bridges, in thirteen days.

Trial of English and French Rifles.—The current number of the "Proceedings of the Royal Artillery Institution" contains an interesting account of a trial lately, at Woolwich, of the Chassepot rifle in comparison with the Henry-Martini. As regards accuracy, it appears that the Chassepot was greatly inferior to the English arm. The worst target made with the Henry-Martini at 500 yards was 1.652 ft., the best with the Chassepot was 2.38 ft. The best target with the Henry-Martini showed a still higher degree of accuracy. viz: .96 ft. The trajectory of the Henry-Martini was flatter than that of the Chassepot, viz., 8 ft. 2 in. against 10 ft. In simplicity of manipulation the English rifle was superior, and it is less fatiguing to use. In firing for rapidity the Chassepot gave 20 rounds in 1 min 42 sec.; the Henry-Martini 20 rounds in 48 sec., or more than twice the rapidity.

New Turkish Iron-Clad —The Moyini-Zaffer, built for the Turkish government by Messrs. Samuda Brothers, at Poplar, was recently launched. The length is 230 ft., breadth 35 ft., depth 27 ft. Her burden is 1,400 tons, and her displacement 2,400 tons. Her armament will be four 12-

ton rifled guns placed in a double central battery, so arranged that they can all be fired on one broadside, or can be trained to fire in a line nearly parallel with the ship's course as bow and stern chasers. She is designed by Mr. Markrow, of the Thames Iron Shipbuilding Company, and will, if the expectatiou of her designer and builders be accomplished, be the fastest vessel of her class afloat.

NEW BOOKS.

Iron and Steel Manufacture: a series of Papers on the Manufacture and Properties of Iron and Steel; with Reports on Iron and Steel in the Paris Exhibition of 1867; Reviews of the State and Progress of the Manufacture during the Years 1867 and 1868; and Descriptions of many of the Principal Iron and Steel Works in Great Britain, the Continent of Europe, and the United States. By Ferdinand Kohn, C. E. New York: Virtue & Yorston, No. 12 Dey street; and D. Van Nostrand.

This handsome volume, which is profusely illustrated, embraces a series of paper on the manufacture of iron and steel; reports on iron and steel in the late Paris Exhibition; reviews of the state and progress of the iron and steel manufacture in 1867 and 1868; together with detailed descriptions of the principal iron and steel works iu Great Britain and on the Continent. . . . The author commences with a general notice of the iron aad steel manufacture in 1867, and in this the method of arrangement adopted in the body of the work is indicated. The first important division is devoted to iron smelting. This introduces much useful information about the Scotch iron field, particularly of the Gartsherrie, Coltness, Govan, and Langloan iron works. Barrow-in-Furness naturally comes in a prominent place, and the extensive works at Wigan are also described. The new district of Cleveland receives, as might be expected, an elaborate notice, the more modern furnaces being fully explained by illustrations. About one-half of this division is appropriated to continental iron works, and to various metallurgical subjects connected with the manufacture of pig iron. The engineering appliances required for blast furnaces—such as hoists, blowing engines, calcining stoves, &c.—come next in review, all the newest arrangements being fully described. A considerable space is devoted to cupolas, foundry cranes, and foundry work in general; the Phœnix Foundry, Glasgow, and the Ormesby Foundry, Middlesborough, being especially noticed. The production of Bessemer steel takes up a great part of the work. Very elaborate details are given of the plant required in carrying on the Bessemer process. Descriptions of the Cyclops Steel Works, Sheffield, of the Barrow, Dowlais, Don, Gorton, Mersey, and other steel works, appear with elaborate illustrations of the most improved arrangement of Bessemer plant. The Siemens-Martin process, now being successfully introduced in this country, is noticed; also half a dozen other processes for the manufacture of steel. The important regenerative furnaces of Mr. Siemens, which are calculated to effect a great economy in the amount of fuel required in heating and smelting furnaces, are naturally described in detail, more particularly as applied in several places to puddling purposes. Coming to the manufacture of wrought iron, we find articles on puddling, including the various attempts that have been made to carry on the process by mechanical means; followed by descriptions of forge hammers, forging presses, and rolling mills. In the latter department, tyre rolling, the universal mill, improved plate mill machinery and adjuncts, form a highly important feature in the volume. If we add that reports on the iron and steel exhibited at Paris, and on various matters connected with the strength and clasticity of iron and steel, are appended to those above enumerated, we have given a tolerably clear sketch of what Mr. Kohn has collected in this quarto volume of 288 pages, with its 83 full page illustrations. . . . The book will, assuredly, be of good service to the trade, particularly those who are practically connected with iron or steel works; and we have no doubt it will have an extensive circulation in all the iron-making districts. —*Iron and Coal Trades Review.*

The Mining Atlas. By Thomas Spargo, M. E., &c. Published by the author, at 224 and 225, Gresham House, Old Broad street, City. For sale by Van Nostrand, New York.

Mr. Spargo has in the present work excelled all his other publications, by the importance of the subjects and the exceedingly interesting manner in which they are treated. No fairy tale could contain a more romantic air, or be written in a more graceful style, than the "Mining Atlas." So varied is the geological, mineralogical, topographical, and geographical information and description that the work is a repertory of scientific information, associated with scenes and incidents, local and historical, of thrilling interest. All the maps and sections are beautifully executed, but that of Colorado territory is a surpassing beautiful specimen of orographical delineation. The literary portion of this number is varied and excellent. Chapter I is introductory and general; chapter II, how mines are worked, and plans and sections are framed; chapter III, general descriptions of the mining regions in Great Britain, of which maps and plans are given in the volume, such as Cornwall and Devon, Cardiganshire, and the Isle of Man; chapter IV, mineral-bearing regions of the American continent, Cardiganshire, Dolcoath Mine, and Botallack Mine. There are 36 quarto pages of literary description and original treatise on the important subjects above named. We strongly recommend not only persons engaged in mining as investors or otherwise, but the whole public to make the opportunity available of procuring what we do not hesitate to pronounce one of the most interesting works given to the public for many years.—*Mining Journal.*

Cyclopædic Science Simplified. By J. H. Pepper, Professor of Chemistry, F. C. S., A. I. C. E., &c. London: F. Warne & Co., Bedford street, Convent Garden. New York: Scribner, Walford & Co., 1869.

Professor Pepper is already known as a writer upon natural philosophy, but his earlier works were written for the youthful student. The volume now before us is an advance upou those, and conveys scientific information to such readers as may have neither the time nor the inclination to study the more recondite authors in such a form as is at once instructive and interesting. In fact, our author transports himself, with all his happy ideas and illustrations, from the lecture theatre to a volume containing nearly 700 pages of letterpress, interspersed with about 600 engravings. The subjects treated of embrace light, heat, electricity, magnetism, pneumatics, acoustics, and chemistry, which are considered in all their varied branches, their practical applications being illustrated. The various natural phenomena are explained with brevity and simplicity, and illustrations are given, by means of which the general reader is at once made familiar with facts and principles, which otherwise would be but "dark sayings" to him. The author introduces here and there portions of papers, by our veterans of science upon the subjects of which he treats. Thus, among others, we find the names of Faraday, Daniell, Wheatstone, Brewster, Tyndall, Crookes, Siemens, Noad, Spillar, &c., whose writings are judiciously quoted in their own words, and are not hashed into a jumble by the pen of a plagiarist. In this work the reader will find reproduced many of those interesting experiments illustrative of the peculiar properties of light, heat, and sound, with which Professor Pepper has been wont to entertain them. In short, as a first progressive book in natural philosophy, and as one eminently calculated to stimulate the reader to a deeper research into scientific truths, we know of none which commends itself so well as Professor Pepper's "Cyclopædic Science Simplified." It is, moreover, a handsomely got-up volume, and does credit to the publishers, who have made the outside of the work as attractive as the Professor has made the inside.—*Mechanics' Magazine*.

LINK AND VALVE MOTIONS. By WM. S. AUCHINCLOSS. New York, 23 Murray street. D. Van Nostrand. [Second notice.]

There are few draughtsmen who are willing to bestow much time on the perusal of books on valve motions, or to give attention to rules for their design. The feeling is well nigh universal that the proportions of the parts can be determined with greater confidence on the part of the designer and with at least equal speed by the usual process of laying out the motion on the drawing board, as by reference to any rules intended to supersede this labor. The work before us, so far as it relates to simple eccentric valve motions, differs from the ordinary run of works of this class in that it does not propose a series of rules liable to be forgotten or misunderstood, but simply shows how the labor usually expended in laying down a proposed motion may be dispensed with and the results arrived at in the absence of all drawing tools. This is done by simple measurement on an engraved diagram which the author has constructed, and which, from its simplicity and convenience, excites wonder that it has not been used before. By means of this the designer can, in less than a single minute, tell what proportions of valve and position of eccentric must be employed to give a desired point of cut off with any length of connecting rod; or can in like manner determine any of the features of the valve motion when the necessary data are given without recourse to any geometrical construction or the study of any rules. In laying out the link motion the conditions are more complex, and here it is necessary to resort to geometrical construction, but the author shows the effect of the different modifications that may be made so clearly that much of the difficulty which, to many, appears inevitably connected with the design of a successful motion of this class, is removed.

The work is plentifully supplied with such tables as are required in the operation of designing valve gear, the effort of the author throughout being to lessen the labor of the designer by performing for him all the preliminary and incidental calculations which arise in such work, leaving him simply to select what is applicable to the particular case in hand. We feel sure that all who read the work will be struck at once with its practical value. S.

THE SMOKE NUISANCE AND ITS REMEDY BY MEANS OF WATER, WITH REMARKS ON LIQUID FUEL. By C. J. RICHARDSON, Architect. Atchley & Co., Great Russell street, Bedford square, London. W. C. For sale by Van Nostrand.

Mr. Richardson's plan for remedying the smoke nuisance is by washing it with the spray of water. He gives it in detail, with diagrams; and he remarks that though it certainly is not possible to disturb the whole of the chimneys of London, the worst of them might be operated on, such as the chief kitchen flues of the great establishments which are continually sending out inky smoke. If it were possible, as he observes, to cut into all the chimneys of London and apply the remedy, the whole of the soot which at present escapes into the atmosphere might be caught and passed into the drains: it would there deodorize them, and the sewage would be rendered doubly valuable as manure, and be largely increased in quantity. This would certainly be the best mode of remedying not only the smoke nuisance, but the sewage emanations also, because so long as the air is contaminated with these, the smoke is at least useful in the air as a deodorizer of them, however injurious to human lungs in itself, or unsightly in its effects on buildings. In the pamphlet under notice, Mr. Richardson gives the results of his important experiments with liquid fuel. The substitution of petroleum for bulky coal in steamers would be an immense improvement, both in our mercantile and our naval shipping. Mr. Richardson says that "any boiler having water space below grate can be fitted to burn oil, so as to obtain a result from $2\frac{1}{2}$ to 3 times above that given by the best coal; 5 times, probably, of that given by common coal: no alteration will be required, only some additional plates in lieu of fire-bars."—*Builder*.

THE HANDBOOK OF IRON SHIPBUILDING. By THOMAS SMITH, M. I. N. A. London: E. & F. N. Spon. For sale by D. Van Nostrand, New York.

We have here a handy little manual, consisting of but sixty-two octavo pages, yet containing within that space a greater amount of useful practical information than is to be found in many works five or six times its size. Mr. Smith states in his preface that his book is intended to serve as a practical guide to shipowners, shipbuilders, inspectors, shipmasters, foremen, and intelligent working men; and it appears to us that it is well calculated to fulfill its end. It contains no elaborate theoretical disquisitions, and, in fact does not deal with theory at all; but contains abundant practical information as to the points to which attention should be paid in constructing an iron vessel. The book is divided into two parts, of which the first consists of practical instructions, while the second contains a variety of useful information, such as the weights of deck-beams, angle iron, plates and rivets, copper bolts, &c., the weight and strength of canvas, the allowances for waste in converting timber for shipbuilding purposes, and a large collection of detailed piecework and other labor prices.

The labor prices form an important feature in the work; they include the standard wages of the various classes of mechanics employed in a shipyard on the Thames, Mersey, Wear and Tyne, and the Clyde; and, as we have said, an extensive collection of the various piecework prices paid in the different districts. To these are added detailed tables of the actual costs for labor and materials of several iron steamers and sailing vessels of various sizes and classes.—*Engineering.*

Appleton's Cyclopædia of Drawing. Designed as a Text-Book for the Mechanic, Architect, Engineer, and Surveyor. Part I. Edited by W. E. Worthen, New York. D. Appleton & Co., 90, 92 and 94 Grand Street.

The system of publishing valuable books in parts by subscription has long found favor with mechanics aud others, and very properly so. The present work, when completed, iu thirty parts, at thirty cents each, will cost, including binding, not less than $10.50 to $12.00, a sum which few mechanics, especially apprentices, would care to iuvest in a single work. But by taking it in parts at thirty cents, many a quarter will be saved which would otherwise be spent for cigars or lager, while the money thus invested will bring in better returns than if it were placed at compound interest. Moreover each part may thus be studied carefully as it is received, and the money need not be invested in any part of the book until that part is wanted. Of course these remarks apply chiefly to our young men, or rather boys who are endeavoring to fit themselves for a future career of usefulness.

Of the character of the work it is hardly necessary to speak. We were familiar with the first edition and held it in very high esteem, and we have no doubt that the author has introduced into this new edition those improvements which a riper personal experience and the general advancement of the art have brought to his notice.—*Manufacturer and Builder.*

Force and Nature, Attraction and Repulsion; the Radical Principles of Energy, Discussed in their Relations to Physical and Morphological Developments. By Charles Frederick Winslow, M. D. Philadelphia: J. B. Lippincott & Co.

We have endeavored, before expressing our views in regard to this book, to read it in a perfectly candid spirit of inquiry. We confess that we found it hard to maintain that spirit to the end. Its style is at times forcible, and its author has evidently caught more than a mere glimpse of certain fundamental truths; but while saying this much, we are compelled to add that it is one of the most illogical books we ever attempted to peruse. It is full of fautastic speculations, and contains not a few errors in its statements of facts. It is wearisome, from its interminable repetitions and its diffuse method of discussion will hardly fail to draw upon it the severe criticism of thinking readers. In short, it is to philosophy what punch is to the palate, full of incongruities; and, although too much diluted by redundant forms of expression, till quite palatable, but not very nutritious. Claiming at the outset to assume nothing, it ends by assuming everything. Written to enunciate what is evidently a pet theory of the author, namely, that repulsion is equal in quantity to attraction, and that the two are co-existent, and the foundation of all material existence, it will convince few; while its speculations will, if we mistake not, draw upon its author a storm of adverse criticism.—*Scientific American.*

Iron: Its History, Properties and Processes of Manufacture. By William Fairbairn, C. E., F. R. S., &c. &c. Third edition, revised and enlarged. Edinburgh: Adam and Charles Black, 1869. For sale by D. Van Nostrand, N. Y.

When Mr. Fairbairn gave the pofession a second edition of his treatise ou iron and steel manufacture, he predicted that great changes would, at no great distance of time, occur in that department of industrial art, and which would result in the production of a superior article. These changes have, to a great extent, occurred, and have necessitated another edition of Mr. Fairbairn's most useful work, which now lies before us. The verification of this prediction has been chiefly accomplished by the extensiou of the Bessemer process, and the gradual introduction of the homogeneous system into the manufacture of metals. Mr. Fairbairn describes all the new improvements, including the Heaton process, which, by the introduction of the crude nitrate of soda, results in the production of "steel iron" from any kind of pig iron. This method of manufacture is described in a chapter which embodies the improvements in the manufacture of iron and steel from 1864 down to the preseut time. The work is fully illustrated, and contains some valuable information upon the properties of the materials of which it treats.—*Mechanic's Magazine.*

Examples of Modern Steam, Air and Gas Engines. By John Bourne, C. E. London: Longmans, Green, Reader and Dyer, Paternoster-row. For sale by D. Van Nostrand.

We have now got half way through Mr. Bourne's work on modern engines, Parts XI and XII being now to hand. In these, as in those which have preceded them, there is no lack of interest. After pointing out the probable course of improvement in locomotives, the author gives a condensed account or recapitulation of the principal classes of improvements in the steam engine, which have been propounded at various times in its history. These are arranged chronologically, dates and the numbers of patents—where patents have been obtained—being given. Thus, independently of the practical observations of the author, we have a very complete index of the subject, which, of itself, will prove of great value to many designers and improvers of steam engines. A large folding plate of Captain Ericsson's original "Monitor," showing the screw and turret machinery, accompanies Part XI, whilst Part XII has two plates, giving the details of surface-condensing engines, by Messrs. Richardsou.—*Mechanic's Magazine.*

The Industries of Scotland. By David Bremner. Edinburgh: Adam and Charles Black, 1869.

During the last year, a series of very interesting articles upon the industries of Scotland appeared in the weekly issue of the "Scotsman." These articles were fair and accurate accounts of the various branches of trade, and we are now glad to see them collected together and reproduced in a more permanent form The volume in question is a history of the rise, progress, and present condition of the Scottish industries, especially of those which, by their extent or peculiarity, merit notice. Mr. Bremner judiciously confines himself to a plain narrative of facts, which have been carefully selected, and are interspersed with here and there a few general reflections. Iron works, coal mines, shipbuilding establishments, railway works, linen and cotton works, fisheries, &c., present themselves in turn.—*Mechanic's Magazine.*

A Treatise on the Teeth of Wheels; demonstrating the best forms which can be giveu to them for purposes of Machinery, such as Mill-work and Clock-work; translated from the French of M. Camus, by John Isaac Hawkins. Third edition. Philadelphia: Henry Carey Baird, 406 Walnut street. Price $3.

The "rule of thumb" has always very extensively governed the construction of toothed gearing, and the consequence is that perfect gearing is very rare in machinery. It is astonishing when we consider the immense saving in friction, wear and cost of repairs, and the greater regularity of operation obtained by the use of gears with properly constructed teeth, that more attention has not been paid to the subject. This little book explains, in such manner as to be intelligible to those who are in the least acquainted with mathematical science, the proper form of the teeth of wheels, and the art of finding the number of teeth which ought to be given to wheels and pinions. It goes very fully into the subject, and is illustrated by eighteen plates of diagrams.—*American Artizan.*

Report of a Special Committee on the Merits of a Proposed Method of Supplying Pure Air to Schools, Churches, Hospitals, Asylums, Dwellings, and all Occupied Houses; also Railroad Cars and Passenger Vessels. Presented at the Regular Meeting of the New York Association for the Advancement of Science and Art, at Cooper Institute, and unanimously adopted, March 8th, 1869.

The pamphlet of which we have just given the title is a singular document—singular for its grammar, and perhaps still more singular from its strange mis-statements of scientific facts.

The "Manufacturer and Builder" thus commences a criticism of some length, and we think it makes out a rather embarrassing case for the unanimous New York Associatiou for the Advancement of Science and Art.

General Problems in the Linear Perspective of Form, Shadow and Reflection: or the Scenographic Projections of Descriptive Geometry. By S. Edward Warren, C. E., Professor of Descriptive Geometry. etc., in Rensselaer Polytechnic Institute. New York: John Wiley & Son, 2 Clinton Hall, Astor Place.

Professor Warren is widely and favorably known as the author of several valuable works on drawing. The present volume ample sustains his previous reputation and must prove not only a most efficient text-book in our industrial schools, but a valuable aid to architects, engineers, and all who have occasion to make accurate drawings.—*Manufacturer and Builder.*

The Millers', Millwrights' and Engineers' Guide. By Henry Pallett. Illustrated. Henry Carey Baird, Publisher, Philadelphia. Price $3 post-free.

This book should be in the hands of every miller. The subject is treated in a plain, familiar manner, free from all unnecessary technical words, and intelligible to those of the most limited education, the general information afforded being almost invaluable to those who have not had an opportunity of judging the best way of milling. The transparent model attached to the work showing the actiou of the furrows cutting wheat and the operation of the millstones is, of itself, worth the price of the book. It is, perhaps, as full and complete a work on milling as has ever been published, and ought to be read by all engaged in the business.—*Milling Journal.*

A Practical Course of Military Surveying; including the Principles of Topographical Drawing. By Capt. Lendy, F. G. S., etc. With an Atlas, mostly by Maj. Petley. New Edition. London: Atchley & Co. 1869. For sale by Van Nostrand.

That this able work has reached a second edition is a practical and well-merited testimony in its favor. The author is director of the Practical Military College at Sunbury; and Major Petley is Professor of Military Surveying at the Royal Military College, Sandhurst. This edition contains many additional plates, etc. The practical part of the work has not been altered, and remains quite elementary, though deemed sufficient for all field purposes. A brief sketch of the operations necessary for a trigonometrical survey has been added.—*Builder.*

Physical Survey of Virginia; her Geographical Position; its Commercial Advantages and National Importance. Preliminary Report by M. F. Maury, LL. D., etc., Professor of Physics, Virgiuia Military Institute, Lexington, Va. Second edition. New York: D. Van Nostrand, publisher, 23 Murray street and 27 Warren street.

This work, besides pointing out the advantages which arise from the geographical position of the magnificent State of Virginia, and which are illustrated by large maps, contains very valuable information as to its climate, soil, and productions, its mineral resources, water-power, and manufacturing facilities, and gives valuable suggestions as to how its industry may be stimulated, its enterprise encouraged, the material prosperity of its people advanced, and its general welfare promoted.—*American Artizan.*

The Parks, Promenades, and Gardens of Paris, Described and Considered in Relation to the Wants of Our own Cities and of Public and Private Gardens. By W. Robinson, F. L. S. London: John Murray.

This is a comprehensive and elegant work, profusely illustrated, and of undoubted value to public and private decorators of parks aud gardens.

Polar Magnetism: A Paper read before the American Institute on the Cause of Polar Magnetism, the Attraction of the Needle to the Pole, the Variations of the Compass, and the Phenomena Incident to the Same. By John A. Parker. New York: Wiley & Son.

Second Lecture on Polar Magnetism: Its Astronomical Origin; Its Period of Revolution and the Synodical Period of the Earth Identical. Read before the American Geographical and Statistical Society. By John A. Parker. New York: Wiley & Son.

These two pamphlets, instead of being a contribution to the stock of public knowledge, are simply an exhibition of the ignorance of the author concerning a subject which appears to have occupied his attention since he published a book of similar calibre, on the quadrature of the circle, some eighteen years ago. This says the reviewer, in the "American Journal of Mining," and he certainly makes out his case, in an article of some length and a good deal of breadth.

The Resources of Missouri, and the Natural Adaptation of St. Louis to Iron Manufacturers. By Sylvester Waterhouse, of Washington University.

This pamphlet, which was published originally in 1867, has recently been enlarged by an appendix on the adaptation of St. Louis to iron manufactures. It contains much that is interesting. The experiment in manufacturing iron at Carondelet affords the data for Professor Waterhouse's conclusions. In the first place, the quality of the pig iron made there is pronounced good by a number of presidents of companies engaged in manufacturing articles of hardware. As to the cost of manufacturing, the pamphlet goes into elaborate statistics and makes out a good case.

Kemlo's Watch-repairer's Hand-book; being a Complete Guide to the Young Beginner in Taking Apart, Putting Together, and Thoroughly Cleaning the English Lever and other Foreign Watches, and all American Watches. By F. Kemlo, Practical Watchmaker; with Illustrations. Boston: A. Williams & Co., 100 Washington street.

This little book should be owned and studied by every young watchmaker and watch-repairer; and it is of value to every owner of a watch, teaching him how to take care of his bosom friend.—*American Artizan.*

To which we may add that the little work is elegantly got up and illustrated, being, in fact, an art book as well as a text book.

French Measure and English Equivalents.—By John Brook. Sheffield.

In a series of compact tables the English values of French measure are arranged from one to a thousand millimeters, and from one to a hundred meters; the fractions of an inch progressing in sixteenths are also reduced to French values. The little book will be found useful to almost every engineer.

Roads, Railways, and Canals for India. By T. Login, Esq., C. E., &c. London: E. & F. N. Spon.

This is a double pamphlet, full of facts, calculations, and suggestions on this important matter, and will no doubt prove of value to all immediately interested in the development of the economic resources of India if not of America.

British Rainfall, 1868: On the Distribution of Rain over the British Isles during the year 1868; with Remarks and Illustrations. Compiled by G. J. Symons, F. M. S. London: Stanhope, 1869. For sale by Van Nostrand, New York.

MISCELLANEOUS.

Heat Necessary to Ignite Vapors.—W. R. Hutton, of Glasgow, has recently determined the degree of heat at which the vapors of a number of liquids catch fire from a burning candle, when it approached to the surface of the fluid at a distance of 1.5in. or 0.5in. The results of these experiments are recorded in the subjoined table:

	Specific weight.	Inflaming Point in Degs. of Fah. At a distance of 1.5in.	Inflaming Point in Degs. of Fah. At a distance of 0.5in.
	Deg.	Deg.	Deg.
Sulphuric ether	747	Below 53	....
Bisulphide of carbon	1.270	do 53	....
Petroleum benzine	706	do 53	....
Benzole from coal tar, 90 per ct.	861	do 74	71
Crude paraffin oil	849	do 74	72
Crude naphtha	884	do 78	74
Whisky	940	do	85
Wood naphtha	9.840	do 87.8	81
Crude paraffin oil	891	do 89	84.2
Crude naphtha	881	do 90	·86
Dutch gin	930	do	90
Wood spirit	827	do 96.8	84.2
Illuminating naphtha	859	do 100	91
Wine spirit	817	do 104	73
Whisky, 15 overproof	893	do 109	83
Whisky, 11 overproof	905	do 110	84.2
Kerosene	801	do 118	110
Light oil from coal tar	920	do 119	109
Spirit from resin	922	do 122	105.8
Turpentine	875	do 130	119
Sherry wine	993	do	130
Port wine	1.003	do	130
Refined paraffin oil	809	do 134	123
Refined paraffin oil	814	do 138.2	127
Fusel oil	850	do 140	129.2
Oil from resin	987	Above 212	....
Heavy tar oil	950	do 212	....

Street Washing and Sweeping.—The following practical remarks were made by Mr. J. K. Fisher before a recent meeting of the Polytechnic Association of the American Institute:

"The superiority of washing streets may be seen by those who observe the following facts:—1st, Fully a third of the dirt is left on the pavement by the machine and hand-brooms in Broadway. 2d, A strong shower washes the pavement clean, excepting where there are holes, in which water remains and sediment falls. 3d, In wet weather the streets are not swept, but mud accumulates for days and weeks; and the mud holds water like a sponge, and keeps the streets wet for days after the sidewalks would be dry, were the mud not tracked upon them. 4th, The best time to wash a street is while it is wet; the washing engine would then use less water. 5th, As soon as rain is over, the washing engines would do their work, and blow the dirty water out of the holes, and leave the pavement nearly dry, so that in half an hour it would be completely dry; thus saving the muddiness, which now lasts from two to six days before the contractor sweeps. 6th, The cost of washing by hose-jet in Sheffield was less than half the cost of sweeping and cartage; proper washing engines would further reduce the cost. The washing would make less dust than sweeping.

"Considering the mud avoided, and the little if any dust, the washing system would give more than double cleanliness, probably at half the cost of the present inefficient system. The washing engines would be efficient fire engines, and would always be ready to leave their street work instantly when fires occur; their cost would therefore be little beyond what is now incurred for engines and men, who do but few hours' work in a year.

"Floating fire-engines could dredge the docks by jet, while the tide runs outward, and thus clear the docks from the street dirt, and at the same time serve as fire engines better than if kept inactive, without steam up and their fires strong.

"Some of our sewer engineers say that the sewer gullies are not made to pass street dirt, but to catch it; and that, therefore, alterations would be required to make this proposed system practicable. Others say that much of the street dirt does go through the sewers. I am convinced, by evidence published in England, that the system is practicable with the present gullies, and that the gully traps are needed to catch the gravel that is often found in streets, and that might do harm in the sewers. Mr. McElroy's paper is good professional evidence against the hasty surmises of engineers who have not studied the subject."

Dates—Amendment in the British Constitution Needed.—According to English newspapers, technical, commercial and literary, no event ever took place on the 20th of July, or the 11th of December, or at any other period absolutely defined in the statement of fact. "Messrs. Samuda launched the ironclad *Vengeance* on Thursday;" "Mr. Scott Russell yesterday lectured the Royal Institution;" "the John Bull won the ocean race, by arriving on Friday;" "a total eclipse of the sun will take place on Wednesday." In rare instances we are favored with a hint in the shape of "next" or "last," but not by polite writers. The man who hopes to be a F. R. S. would utterly ruin his chances by writing "Wednesday last;" and there is not an engineer's apprentice in Great George street who dares write "Thursday July 1st," in an article intended for publication.

Nicholas Woods, the wonderfully versatile and remarkably accurate reporter for the "Times," who does with equal elegance an armor test at Shoeburyness one day and a marriage at St. George's, Hanover Square, the next; a hanging at Old Bailey in the morning and the trial of a surface condenser at the Isle of Dogs in the afternoon—Woods is a precedent and a pillar in the British Constitution. Woods says in the "Times" that a thing happened "on Thursday," and even Colburn does'nt quite like to add "July 1st," for, independent as he may be in his professional convictions and expressions, an un-Woodsy style of reporting a fact would be as inexcusable a violation of British precedent as traveling in cars that were not locked, or crossing the channel with the decency and comfort of Long Island Sound navigation.

Seriously, this almost universal omission of dates in the English papers is as unnecessary as it is inconvenient. One has to find the date of the paper and compute the time, unless, as is often the case in newspaper offices, one happens to be reading a slip without date; but when a technical weekly or monthly copies *verbatim* from a *daily* about the trial that was completed "yesterday," or the ship that was launched on "Thursday," this affectation of the cockney-daily style becomes ludicrous as well as embarrassing.

Subjects of British Letters Patent for 1868. Mr. George Shaw has drawn up a condensed analytical list of letters patent for inventions granted and provisional protections applied for during the year 1868. From this summary of inventive effort we subjoin an indication of the progress discernible in materials and appliances connected with building trades. In all, there were 3,991 applications. Of this large number 11 related to improvements or inventions connected with sewers, drains and cesspools; 13 with making and sweeping roads; 38 appertained to wheels for railway and other carriages; 4 to docks, breakwaters, and submerged works; 84 to furnaces and consuming fuel; 116 to railways, locomotives and railway carriages; 185 to steam engines and steam boilers; 33 to artificial fuel, matches and splints; 6 to baths; 4 to bells and bell-hanging; 2 to castors for furniture; 32 belonged to latches, hinges and springs for doors; 5 to fenders, fire-iron and fire-guards; 39 to nails, bolts, screw-nuts, and rivets and machinery for manufacturing the same; 21 related to the processes of sawing, planing, boring, etc., stone and slate; 54 to sawing, planing and turning metals, wood, etc.; 79 to telegraphs, signals and intercommunication in railway trains; 4 to surveying instruments; 14 to drawing, painting, and exhibiting pictures and photographs; 31 to windows, sashes, shutters, doors and fencing; 3 to floors and flooring machinery; 52 to tunnels, bridges, arches and portable and other buildings; 21 to lime, brick, and other kilns and coke ovens; 10 to artificial stone, plaster and cements; 30 to bricks, tiles and clay-pipes; 13 to glass manufacture; 19 to blinds, curtains and shades; 43 to stoves, grates, fire-places, kitchen ranges and culinary apparatus; 30 to warming and ventilating buildings; 11 to gas-burners; 33 to gas and water meters and regulators; 43 to cocks, taps and valves; 31 concerning pipes and tubes for steam, water and gas, and joints for the same; 21 related to water-closets and urinals; 16 to hydraulic machinery for raising and distributing water; 5 treated of the preservation and preparation of timber; and 2 apportioned to coffins, hearses, and preservation of the dead. Satisfactory as this amount of activity thus indicated may be, it appears trifling to that fermenting in men's brains on the other side of the Atlantic.—*Builder*.

The Guibal Fan.—A large fan, on the Guibal principal (see Van Nostrand's Magazine, No. 1, page 43), was recently started at the Byers Green Colliery, and did good work. It was run up to 60 revolutions per minute, and at this speed produced 68,000 cubic feet of air per minute, with a water gauge of 3.10 in. The quantity of air previously got by the furnace was 11,000 cubic feet below the quantity produced by the fan, or 57,000 cubic feet. The fan has not yet been worked up to its maximum power, as it is guaranteed by the maker to work up to seventy revolutions per minute. The makers are Messrs. Black, Hawthorn & Co.. of Gateshead.

LONG SPAN BRIDGES.—Prof. De Volson Wood has furnished the following interesting summary to the "Journal of the Franklin Institute:"

TABLE OF BRIDGES HAVING LONG SPANS.—*Trussed Bridges.*

NAME OF BRIDGE.	Total length in feet.	No. of spans.	Longest span.	REMARKS.
Schaffhausen, Switzerland	365	2	193	Weisbach Mech. vol. II, p. 283.
Trenton, N. J	880	5	200	Wooden arch trussed. Haupt on Bridge Construction, p. 242.
Columbia, Penn'a.............	5,280	29	200	Burr's; destroyed during rebel invasion, 1863. Mahan, p. 240.
Newark Dyke, Eng............	......	......	240½	Longest span of Warren's Girder. Jour. Frank. Inst., vol. 26, 3d series, p. 156.
Essex, Mass....................	250	1	250	Mahan, Civ. Eng., p. 238.
Chepstow, Eng.................	606	4	306	Queen Past—Theory of Bridges—Weak.
Noget, E. Prussia.............	374½	2	321	Jour. Frank. Inst., vol. 39, 3d ser. p. 230.
Upper Schuylkill..............	......	1	340⅓	Mahan, p. 237.
Louisville Bridge, over Ohio river,	5,201	25	370	Fink's Truss—Report of Committee.
Wettingen, Germany,...........	390	1	390	Erected in 1778. Longest span of wooden truss on record. Weisbach Mech. vol. II, p. 83.
Dirschau, Prussia	2,383½	6	397¼	Iron lattice. Jour. Frank. Inst. vol. 39, 3d series, p. 230.
Kuilmburg, Holland	......	......	515	Longest span trussed bridge. Official report, 1866.
Derry, designed by Claus (never built)......................	......	1	900	Proposed wooden structure. Weis. Mech. vol. II, p. 84.

Tubular Bridges.

NAME OF BRIDGE.	Total length in feet.	No. of spans.	Longest span.	REMARKS.
Conway, Eng..................	......	1	400	Civ. Eng. Jour., 1848.
Britannia, Eng.................	1,513	4	460	Tubular bridges by Dempsey. Traité de la Construction des Ponts Métalliques, pl. X.
Victoria, at Montreal, Canada....	10,284	25	330	Hunt's Merch. Mag., vol. XXXI, p. 504; 24 spans are each 242 feet.

Arched Bridges.

NAME OF BRIDGE.	Total length in feet.	No. of spans.	Longest span.	REMARKS.
Neuilly (over Seine)............	*640	5	128	Mahan, p. 225.
Teff, South Wales..............	. ....	1	140	Failed by rising of the crown. Woodbury on the arch, p. 432.
London Bridge.................	784	5	152	Woodbury, p. 432—for railr'd purposes.
Rica, Ayr.....................	......	......	180	Jour. Frank. Inst., vol. 39, p. 231.
Chester or Grosnover...........	......	.....	200	Mahan, p. 228.
Great Washington Aqueduct.....	......	......	200	Sc. Am. 1860, p. 86. Cast iron, by Rennie.
Southwark	......	......	250	Smile's Lives, Eng., vol. II, p. 188.
Trizzo Adda....................	251	1	251	Longest stone arch on record. Treatise on Bridges, Weale, vol. I, p. 48.
St. Louis Bridge...............	1,509	3	515	Not yet built. The arch to be of steel. Rep. by the Co., 1858.
Proposed bridge over the Thames, by Telford..........	......	1	600	To be made of iron. Weisbach, v. II, p. 86.

* More than 640.

Suspension Bridges.

Name of Bridge.	Total length in feet.	No. of spans.	Longest span.	Remarks.
Niagara Carriage Bridge	....	1	1,264	Sc. Am., vol. XX, p. 218. This bridge is about a mile below Niagara Falls.
Cornwall (proposed to be built across the Hudson river, 42 miles above N. Y. City)......	2,409	1	1,600	Jour. Frank. Inst., vol. LVII, p. 165.

Name of Bridge.	When built.	Span.	Remarks.
Douro, at Oporto	1842	558	Sup. to Weale's Bridges, p. 144.
Menai, Eng................................	1825	580	Chain cable. Mahan's Civ. Eng., p. 255
St. John's, N. B..........................	1852	622	Sc. Am., June 19th, 1862.
Nashville, over Cumberland..............	1850	656	Destroyed by rebel Gen. Floyd, Feb 1862. Sc. Am. Mar. 30th, 1850.
Pesth, over Danube	1849	670	Total length, 1250. Jour. Frank. Inst., vol. XVII, 3d series, p. 300.
Niagara Railroad Bridge.................	1854	822	Jour. Frank. Inst.
Fribourg, Switzerland...................	1834	870	Jour. Frank. Inst., vol. XXIII, 2d series, p. 141.
Lewiston (7 miles), below Niagara Falls ..	1856	1,043	Sc. Am., June 1st, 1861. Blown down Feb. 1864.
Lexington and Danville Railroad Bridge...	1856	1,220	Jour. Frank. Inst., vol. XXXIX, 3d series, p. 230.
East River Bridge, N. Y. City............	......	1,600	Proposed. Jour. Frank. Inst., vol. LXXXIV, p. 243.

Root's Pressure Blower.—This device is now, by general consent, here and in England, one of the best, if not the very best means of blowing cupola furnaces. A pair of reciprocating pistons afford, of course, a steady blast of any desired pressure; but they are costly to construct, and the piston packing and valves are subject to wear. No fan blower can be depended upon to give the requisite pressure, viz: half a pound to a pound per square inch—a pressure indespensable to continuous melting, as in the Bessemer manufacture. Rotatory blowers with sliding pistons or rubbing surfaces of any kind, may indeed be kept tight if constructed with sufficient cost, and carefully cleaned and lubricated. The advantage of Root's rotatory blower is that it has, strictly speaking, no rubbing surfaces. The floats, or rotatory pistons, are so shaped that the projections of the one exactly fit into the hollows of the other, without the need of sliding vanes. There is of course a very thin space between the floats, through which a thin film of air leaks back, but this loss is reduced to a minimum by means of a stiff paint or plaster of black lead and tallow, which is applied to the floats and soon moulds itself to fill the spaces that would otherwise promote excessive leakage. But, as in all other machinery with which we are acquainted, the best materials and workmanship pay best in the long run. The shrinkage or the loosening of the wood forming the floats, by reason of improper seasoning or fastening, soon cause excessive friction as well as leakage. Perfectly seasoned wood floats, secured as well as they *can* be to steel shafts and cut gearing, certainly answer well; this we know from experience with not less than three of these blowers, of the largest sizes. At the same time, we think the extra cost of cast-iron floats, planed or dressed by special tools and gauges to a perfect fit, and revolved by several sets of wide-faced cut gears, so as to avoid back lash and wear, would pay. The power wasted in driving a noisy or leaky blower, would cost more than the most accurate construction.

Elastic Collodion Cement.—Ordinary collodion is made by dissolving eight parts of gun-cotton in one hundred and twenty-five parts of ether and eight parts of alcohol. When used as a cement or varnish it becomes very hard, cracks easily, and peels off. It may be rendered elastic by the addition of four parts of Venetian turpentine and two parts of castor-oil. When intended for surgical purposes, as a varnish, which when dry forms a perfectly close-fitting plaster, it has been found that the addition of some glycerine to the ordinary collodion, in which it is dissolved to a small extent, makes a varnish which adheres strongly to the skin, does not crack, and, on account of its elasticity, does not crease the skin.

Wire-Rope Transport.—The practical value of the wire-rope transport system, invented by Mr. C. Hodgson, C. E., (see V. N's. Mag. Vol. I, p. 334,) is now being recognized by those engaged in working mines. Sir G. S. Robinson has given an order to the Wire Tramway Company to construct one of their patent ways, for carrying iron ore from his quarries to the Cransford Station.

ARTIFICIAL STONE.—Mr. Hodgsol, the proprietor of four patents on artificial stone, exhibited his process for manufacturing this stone at a late meeting of the Polytechnic Association of the American Institute. The stone consists of sand cemented together by means of oxalate of lime. The inventor takes two or three parts of sand to one of lime, or rather lime slacked with a solution of oxalic acid. The materials are carefully mixed and then pressed in a mould, where they quickly set. The articles are then transferred to a bath containing a solution of oxalic acid, where in a short time they become hard. Oxalic acid forms with lime a compound of great insolubility. Indeed, the oxalate is the most insoluble of all the salts of lime. A great deal has been said about the superiority of the cements made by the ancients. This is due partly to the influence of time, and partly because the poor cements have disappeared. When lime and sand are left in contact for many years a chemical union takes place, and a true silicate of lime is formed. Hydraulic cement requires the presence of alumina. The Rosendale cement contains carbonate of lime with silica, alumina and magnesia. The French, in making the Suez Canal, employ the mud of the lakes, the sand of the desert and lime, which they mix, bake in the sun and use for the construction of piers, etc., without the application of any fire. This stone is about equal in hardness to Cayenne stone.

ELECTRO-MAGNETIC ENGINES ON BOARD SHIP.—Mr. John Tawse writes to "The Engineer" as follows: Some years ago, when in India, I had a boat on one of the salt lakes of the Coromandel coast, and from experiments I then made I became impressed with the idea that there is an immense mechanical power lying dormant in the simple and natural *galvanic action of salt water on the sheathing of vessels.* Electro-magnetism has hitherto failed as a motive power on the score of economy only. The form of battery used is too expensive, owing to the use of strong acids acting upon a comparatively small surface. Also in this case the electric current is deficient in quantity for mechanical purposes. What seemed to be wanted was a very large area of metallic surface, acted upon by an excitant strong enough to evolve a powerful current, yet not sufficiently so to wear or corrode the plates in a very perceptible degree. I have since published the idea which this gave birth to in several of our scientific journals. But as I have now worked it out to completion, both by calculation and experiment, I detail it herein for the information of your readers.

A vessel to be fitted with an electro-magnetic engine attached to an ordinary shaft, is sheathed on one side with copper, and on the other side with zinc. The sheathing is laid on over sheets of gutta percha in order to insulate it from the woodwork of the vessel. The nails necessary for this purpose are driven in such a manner that they are nowhere in metallic contact with any part of the sheathing. The two sections of copper and zinc sheathing thus form a battery, acted upon and excited by salt water alone. If any one acquainted with the subject will calculate the result of galvanic action on so large a surface as the area of immersion of a floating vessel, they will perceive that it is the right application of it alone that is wanted to convert it into a powerful mechanical force.

The vessel being so sheathed, a wire from each section of course conducts the current to the electro-magnetic engine. In my first experiments I had a large magnet to work a keeper in connection with a crank in the usual way. Since then I have adopted a mode of multiplying the power enormously. Thus the wires are connected with a thick, small-sized electro-magnet in the first instance. In front of its two poles an armature is made to rotate with great velocity, and the augmented current thus produced is carried to an arrangement of two very large magnets working reciprocally in such a way that the keeper, or soft iron beam between them, which works the crank axle of the screw, flows the current into each separately at every stroke, charging it just before the moment of contact. As regards the wear of the plates, it would be no greater than in the case of ordinary sheathing, with this advantage, that no sea-weed or barnacles would adhere to sheathing in constant galvanic activity; ordinary copper sheathing would be quite free from them if the galvanic circle were complete. In fitting the above engine to a vessel the rotating armature working before the first magnet would have to be driven by a small steam engine.

ON THE COST OF WATERWHEELS IN ENGLAND. Mr. Robert Sanders writes to the "Mining Journal" as follows: After fifteen years' practical experience in working all kinds of mining machinery by waterwheels, I am prepared to assert that a wheel 10 ft. in diameter, 3 ft. breast, should not cost about 10*l*.; one of 24 ft. diameter, 4 ft. breast, 120*l*.; or one of 40 ft. diameter, 3 ft. breast, 220*l*. I will quote one instance just to show something about the price of waterwheels. At the Carmarthen United Lead Mines, in South Wales, I had two wheels erected, one of 34 ft. diameter, 3 ft. breast, with cast-iron axles, centers and shrouding; the arms, soling and buckets were of yellow pine; there were also the crank-pin and connecting-joint for sweep rod. The other was 24 ft. diameter, 4 ft. breast, with cast-iron axle centers and shrouding; the arms, soling and buckets were of red, or pitch, pine; also crank-pin, connecting-joint, etc. Both of these wheels were made per contract. The cost of each, including erection, was as follows: 34 ft. diameter, 164*l*. 10s.; 24 ft. diameter 119*l*. 10s. The latter, including wheel-pit, etc., when ready to work, cost altogether 144*l*. The former had no wheel-pit, but worked on a frame, like a grindstone, made of American pine log, and the whole expense when ready to work did not exceed 230*l*.

HOW TO TEST THE LUBRICATING POWER OF OIL. It is a matter of importance to the mechanic to be able to say what amount of friction a particular oil can overcome as compared with another oil. This is done by an apparatus called an "oil-tester," of which a new form, devised by Mr. T. R. Shaw, is thus described: On a vertical shaft fitted in bearings is fixed a disc, on the upper surface of which rests a circular or partly circular block, the two surfaces in contact being preferably finished as true plans. The lower disc is caused to revolve rapidly by suitable means, the continued rotation of the block being prevented by a cord, one end of which is attached to the side of the block, the other end being attached to a spring balance, or to a weighted and gradual lever. The block is kept in position on the revolving disc by means of anti-friction bowls, which are so applied as not to interfere with the rotation of the block. A thermometer is fixed in the center of the block. A small portion of the lubricant to be tested is applied to the disc, the metal block is placed in position, and the lower disc is caused to revolve until a certain temperature which has been fixed upon as suitable for all seasons, as for example 70° Fahr., is indicated by the thermometer, when the test of the oil is commenced by noting the frictional resistance indicated on the scale of the spring balance, readings being taken from the scale at intervals during the continuance of the experiment.—*Scientific Opinion.*

The Velocipede as a Mechanical Agent.—The practical value of the velocipede as a means of locomotion has been thoroughly discussed in a well-considered paper by Mr. Lauder, C. E., read before the Liverpool Polytechnic Society. As advantages and disadvantages of bicycles, tricycles, etc., are very equally balanced as compared with each other, Mr. Lauder's conclusions may be considered to apply equally to all kinds of velocipedes. The velocipede possesses *no* advantage; that is to say, a man can, with equal exertion, walk or run quite as far in a day of eight hours as he can travel with a velocipede in the same time. Mr. Lauder, being a velocipedest himself, has given the velocipede all the advantage in the argument that was at all possible; yet he can only show that, although for a journey of a few minutes duration a speed of 24½ miles per hour may be obtained, no more than 30 miles in the day of eight hours can be traversed. Mr. Lauder is of opinion that, as a means of traveling, the velocipede has very little chance of coming into use, although as an instrument of healthful exercise it is worthy of consideration.—*Builder.*

Speed in Travel.—In a single second a snail travels one five-thousandth of a foot; a fly five feet; a pedestrian, at ordinary gait, five and three-tenths feet; a camel six feet; an ordinary breeze ten feet; a rapid running stream twelve feet; a trotting horse twelve feet; a whale twelve and three-tenths feet; a fast-sailing ship fourteen feet; a reindeer, with sledge, twenty-five feet; a locomotive engine twenty-nine feet; a skater thirty-six feet; a race-horse forty-one feet; a tempest fifty feet; a swiftly thrown stone fifty feet; an eagle ninety-five feet; a carrier-pigeon four hundred and eleven feet; a rifle ball one thousand five hundred and ninety-five feet; a twenty-five pound cannon ball two thousand two hundred and ninety-nine feet; a point of the earth on the equator two thousand four hundred and fifty-one feet; the center of the earth around the sun four miles; a ray of light one hundred and ninety-five thousand miles.

Atmospheric Signal for Ships.—Messrs. MacIver and Co. have introduced Messrs. Wier and Co.'s atmospheric telegraph signals into the Scotia and other large steamers of their fleet. The apparatus may be briefly described as consisting primarily of a small air-chamber to which air has perfect access. In this chamber an elastic disc is placed which, acted on by a lever, compresses the air in the chamber and propels it through a metallic tube of small diameter to any part of the ship with which it is considered desirable to communicate. The air so propelled rings a signal bell in the first instance to secure attention to the signal transmitted; the action of the transmitted air at the same moment that it strikes the bell lifts a small and delicate opaque shutter, revealing under it the word or words of the intended order. The chief point where directions must be given is the locality in which the commander of the vessel is placed, such as the bridge in the case of an ocean-going steamer. Here the handle of the instrument is placed, the whole revolving on a pivot, so that the handle is pressed down to the point which will indicate at a distance the command issued. This is guided in the mode of working by a dial inscribed with the words intended to be communicated.

Proposed Canal Between the Bay of Biscay and the Mediterranean.—The project of establishing through the Valley of the Garonne (France) a canal for large navigation has often been mooted; but there is now a new plan for this undertaking, under the auspices of M. Staal de Magnancourt. The proposed canal will admit not only merchant ships of the heaviest tonnage, but also men-of-war and transatlantic steamers. A port is to be established in the Gironde, just below Bordeaux, and another on the Mediterranean. The cost of the scheme is estimated at 442,000,000f., and the cutting of the canal would occupy six years. The plan, if carried out, will materially shorten the navigable communication between England, the north of Europe, and India, for it will in fact be a continuation of the canal of Suez.

The Fast Voyage of the Scotia.—The Cunard mail paddle-steamer Scotia still continues to maintain her supremacy on the Atlantic. Her last passage from New York to Liverpool was one of the shortest on record, she having made the run to the Mersey, including detention at Queenstown, but allowing 4 hours 40 minutes for difference of time, in 9 days and 19 minutes. She had S. S. W. wind on the day of sailing and afterwards moderate easterly breezes throughout. On the 13th she had logged 254 miles, 14th 326, 15th 330, 16th 322, 17th 31, 18th 641, 19th 340, 20th 320, 21st, to noon, 339, being an average speed of nearly 14 knots an hour. The engines of the Scotia are of great power, and with moderate winds she leaves all competitors far in the distance. The Inman screw steamer City of Paris and the Cunard screw steamer Russia are the only two ships which at all approach her in point of speed.—*Engineering.*

Iron Ship Building in New York.—An estimate was recently obtained by a New York shipping firm, for the building of a first-class iron sailing vessel in this country, but it now appears that the vessel is to be built in New York, more favorable terms having been obtained there, and that only the wire rigging, anchors and chain cables, are to be supplied from England. This, we understand, will be the first American built iron sailing vessel to cross the Atlantic.—*Mechanics' Magazine.*

New Fairbairn Engines.—The Fairbairn Engineering Company have now in hand, and will be shortly ready to exhibit, a set of 60-horse engines, constructed upon an entirely new principle, which, besides possessing other important advantages, will consume probably less than half the quantity of coals required by the best steam engines at present in use.—*British Enthusiast.*

No. IX.—SEPTEMBER, 1869.—Vol. I.

PAYING AND NON-PAYING LOAD.

A paper read before the Civil and Mechanical Engineers' Society, by Mr. B. Haughton, C. E., on "The paying and non-paying weights pulled by the locomotive engine in 1867."

The railway statistics published by the Board of Trade, annually, as far as they go, are of vast importance in determining the quantity and cost of the useful work done by the locomotive. In a country such as the United Kingdom, possessing 14,247 miles of railway (or 22,091 miles of single line), which has been made at a cost of £502,263,000, equal to £35,253 per mile (or £22,736 per mile of single line); in which the receipts from railway traffic are £39,480,000 per annum, or £119,636 per day (in all such calculations I assume that the year contains 330 working days); in which 287,688,000 railway trips (not including those of season-ticket holders) are made in the year, equal to 871,781 trips each day, each trip 12¾ miles in length; in which 148,253,800 tons of goods, minerals, etc., are carried per annum, equal to 449,250 tons each day, each ton pulled over say 25 miles; in which 6,328,490 trains are started per annum, equal to 19,177 trains each day; in which the locomotive travels 148,542,827 miles per annum, or 450,129 miles each day; which has been the cradle of the railway, and in which it and its complement, the locomotive, were first invented, constructed, and brought into operation—in such a country the question of the administration and conduct of the railways must be a paramount one; and we cannot, as its people, be said to have done justice to this magnificent piece of mechanism until we shall have so investigated its economy, and the science of its action and effort, as to place beyond dispute the laws of its existence.

It is particularly desirable that such should be studied at the present day; there is, just now, a lull in the railway atmosphere; railway construction, incessant for the last 40 years, has at length ceased; the engineer is idle, the capitalist, without whose co-operation he dare not lift his hand, stands aloof; the public look on and suffer from the estrangement, and their occupation in this department of their manifold labors being gone (for the construction of 552 miles of single line per annum since 1827, with its attendant expenditure of £12,500,000 yearly, must have been to them a source of much and very profitable business); they began during their enforced leisure to examine and criticize the natural history of the giant that they have created, with the view to bending him to a more tractable and economic servitude; and, in truth, most wildly and inconsiderately have they approached the investigation. We cannot altogether blame them for having placed themselves so far under the guidance of *doctrinaires.* He who, by virtue of his office, ought to have been their guide in their attempt to solve the various questions at issue has not come forward to assist them with his counsel, and out of his practical and special knowledge of the situation. The engineer, which an immense material developement in the current century has produced, has been so entirely absorbed in, and devoted to, the physical side of the railway question, that he really has not had time to consider its moral aspect. As soon as he shall have done so, and explained the condition of affairs, we may reasonably expect that the aforesaid public will become contented with "things as they are," as the intelligent British public always is, when light is given to it, and when it is made aware by the logic of facts that "things cannot be otherwise."

I hardly ever remember to have seen the truth so persistently distorted as of late, by certain pamphleteers, magazine writers, and ambulatory orators, in regard to this question. In one case a most elaborate literary picture has been drawn, in an article styled "The Great Railway Monopoly," the object of which appears to be to induce the Government to undertake the management of the railways of the United Kingdom; to confer upon the traveling public the benefit of low fares; and to prove indirectly the total incapacity of those who have the control and direction of the railway *menage* of the country. The article is remarkable for the display of much research, and, in short, conveys the idea that it comes from the hand of an accomplished and fluent compiler. It, however, reminds the engineer of a grand and boldly designed arch of masonry under construction; it is perfect as to the material selected, its foundations are on a rock, its abutments, its counterforts and haunches are undeniable, but it fails to support itself on the withdrawal of the centering, because of the omission of one simple, though indispensable feature—the key—which, in the case of this slap-dash article, must be supplied by the engineer, and the absence of which stamps the writer as being a literary conjurer rather than a practical man. With such instructors as these alluded to, and the magicians of the Belgian State lines, it is not to be wondered that the English public are disturbed as to the condition of their railways. It is not surprising that, at the first blush, they should believe themselves to be the victims of a selfish association of monopolists, and that this immense property is tended and controlled by an executive of quacks, who are guided by the leading idea that high fares alone will generate income; never was a more unfounded belief fostered.

The railways of the United Kingdom, at the present day, are conducted by an accomplished, scientific, and highly skilled body of experts, who know their business, do it, and don't talk about it, and who, moreover, take out of the locomotive all they can, and present it freely and exuberantly to those whom it is their interest, as well as their pleasure to accommodate—the traveling community; as shall presently be shown, this is, as the "Times" has lately stated, "the best served traveling community in the world," though I cannot endorse the final phrase in the sentence, that it is "the most ungrateful," because ingratitude is a vice of the weak and the unintelligent, and I cannot admit that my countrymen belong either to the one or the other class, but the rather that, having been made aware of the actual condition of affairs, they will accept it as being, on the whole, the best possible, considering all the circumstances of the case, and will unite with those who are only too well pleased to be assisted by them in concerting means for the elimination of such minor defects of the railway system as exist, and which are only those that belong to every human institution, but which, nevertheless, we must combat unceasingly, so as to attain as much perfection as our knowledge of the science involved will admit.

To begin, accordingly, the work done by the locomotive in 1867, the last year for which the Board of Trade returns have been published, was, viz:

3,924,624 passenger trains pulled 19.08 miles each.

	Tons.	Per cent.
Paying weight	27,472,368	4.89
Non-paying weight	533,748,864	95.11
	561,221,232	100.00

2,403,866 goods trains pulled 30.64 miles each.

	Tons.	Per cent.
Paying weight	146,635,826	30.34
Non-paying weight	336,541,240	69.66
	483,177,066	100.00

6,328,490 total number of trains pulled 23.47 miles each.

	Tons.	Per cent.
Paying weight	174,108,194	16.67
Non-paying weight	870,290,104	83.33
	1,044,398,298	100.00

Horizontal mile tons.

Passenger trains	10,708,101,106
Goods trains	14,804,545,302
	25,512,646,408

This work was done by 8,619 locomotives, showing work done by each, per annum, 2,960,047 horizontal mile tons; work done by each, per day, 8,969 horizontal mile tons, equivalent to 382 tons pulled 23.47 miles per day, and further, 17,234 miles run by each engine per annum.

Taking the 23.47 miles, the actual average distance run by each train per day, as consisting of an ascending gradient of 1 in 300 for half the distance, or 11.735 miles, and a descending gradient for the remaining half; and assuming 26 miles per hour to be the average speed of each train, equivalent to an exercise of horse-power, as under:

Train mileage of Board of Trade Returns.

$$\frac{148,542,827}{3,924,624 + 2,403,866} = 23.47 \text{ miles run by each train per day.}$$

Total train tons.

$$\frac{1,044,398,298}{3,924,624 + 2,403,866} = 165.03 \text{ tons' weight of each train.}$$

Average inclination, 1 in 300 up for 11.735 miles; and 1 in 300 down from the same distance.

Average speed, 26 miles per hour.

From these data are obtained the results:

$$\frac{26 \times 5,280}{60} = 2,288 \text{ ft. run by train in 1 minute.}$$

$$\frac{2,288}{300} = 7.626 \text{ ft. lift of train in 1 minute.}$$

$$\frac{165 \times 2,240 \times 7.626}{33,000} = 85.41 \text{ horse-power due to lifting the trains.}$$

$$\frac{165 \times 9 \times 2,288}{33,000} = 102.96 \text{ horse-power due to friction, etc., at 9 lbs. per ton.}$$

$+85.41+102.96=+$ 188.37 horse-power required in ascending the incline.

$-85.41+102.96=+$ 17.55 horse-power required in descending the incline.

$+188.37+17.55=$ 205.92 horse-power exercised throughout the average run of 23.47 miles.

Trains. Trains per day.

$$\frac{6,328,490}{330} = \frac{19,177}{8,619} = 2.22 \text{ trains pulled per day by each engine.}$$

Each train pulled 23.47 miles, at 26 miles per hour, gives 54.16 minutes occupied in the average journey.

$$54.16 \times 2.22 = \frac{120 \text{ minutes.}}{60} = 2 \text{ hours}$$

205.92 horse-power $\times$ 8,619 engines $=$ 1,774,824 total horse-power exercised for two hours each day of 330 days per annum, in behalf of the traveling public.

Considering that these engines may be held on the average to be capable of exercising 400 horse-power each without forcing; the 206 horse-power actually made available will perhaps be considered too small a percentage to take out of each engine, but it will be understood that it is not possible to render useful the maximum power of the total number of engines in the country, for these reasons: that a certain portion must be held in reserve in case of ordinary accident to running engines; that another portion will be engaged as bank engines, and in shunting trains about the stations; that a large proportion of the whole will stand in the sheds for cleaning, and in the shops to undergo the repairs due to the daily wear and tear of an exceedingly complicated and perishable machine; and that, over and above all these requirements, an ultimate reserve will be necessary in order to make sure that a provision shall exist against all eventualities, and that in no possible case shall the company fail to perform their duties to the public punctually, as advertised in the time bills. These results cannot be taken as illustrating the work to be gotten from individual engines, but only as being useful in comparing the total work of one year with that of another in the same country; in comparing the work done in one country with that in another; and, above all, and eminently, in showing a people how much they take from their machinery in gross, with the object of exhibiting the weaknesses of the system, so as to effect such reforms as shall lead to improvements in organization and administration therefor.

In reviewing the foregoing figures, I shall ask your attention to two salient matters therein exhibited, the first of which is that I have reduced the work done to horizontal mile tons, and that I believe this to be the only true mode by which a railway company can accurately test the nature of its operations; and, secondly, to the extraordinary preponderance of the figures indicating the non-paying weight pulled as compared with the paying weight, viz: Firstly, the usual mode of estimating the work done, as practiced by boards of directors, is that by train mileage. The train mileage of one half-year, exceeds that of the corresponding half in the previous year, and this is hailed as a matter of congratulation from the chairman to his proprietors; or the increased income per train mile of the half year has exceeded that of the corresponding six months of the former year by a certain percentage, which is equally a cause of satisfaction to his audience; whereas, it is quite within the range of possibility, and has no doubt happened before now, that each of these apparently pleasing results of the half-year's work has been nothing less than a captivating illusion; for, in the first case given, that of an increase of train mileage, the latter may have increased without bringing an increase of revenue, and may have brought with it a positive loss; and, in the second case, that of an increased income per train mile, the same may have arisen in consequence of a reduction of mileage, and may have existed co-incident with a falling off of revenue. The train mile is not a measure of the useful work done, because the weight of the train is not told; given the weight of the train, however, subdivided into its paying and non-paying weights, and a basis of calculation is afforded, which places the work done beyond cavil.

In order to attain this object, it will be necessary that the paying and non-paying weights of each train started shall be registered, as well as the distance traveled by each vehicle. This, though causing some extra office work, will amply pay for itself in the long run. I have endeavored to reduce the work done, as given in the Board of Trade statistical tables, to the horizontal mile ton by rating the weights of the average trains of the year as follows. It will be observed that some of the items in the tables are assumed. I have determined their value as best I could, from the most reliable sources I have been able to consult; the remaining items are taken from the Board of Trade returns, viz:

Weight of the average passenger train in 1867—

Non-paying load.		
Engine and tender............	50 tons.	
Seven carriages	56 "	
Two breaks..................	10 "	
		116 tons.
Empty carriages, etc., to be pulled back, say $\frac{1}{6}$th of above		20 "
Paying load.		
73 passengers, with luggage, etc., at 2 cwt. each......................		7 "
Total		143 tons.

I have chosen seven as a fair average figure for the carriages to each train. This number of composite carriages should contain, if full, 196 persons, narrow gauge; and in corroboration of this rating, I may quote Mr. Robert Stephenson, who, in his address to the Institute of Civil Engineers, in 1866, rated the then trains as capable of holding on the average 200, while not actually carrying over 100 passengers. It appears, from the Board of Trade returns, that the number of passengers has decreased since then, doubtless owing to competition, and the wish to render traveling more attractive by the running of an increased number of trains, since only $73\frac{1}{4}$ passengers were carried per train in 1867; or it may have been more directly due to the practice of sending through carriages to all the principal stations with the more important trains, thus saving their occupants the necessity of changing from one carriage to another *en route.* The empty carriages to be pulled back with their attendant portion of the weight of the engine, consequent on the irregularity of flow of the streams of traffic in opposite directions, is a fact that cannot be evaded, I have rated it at one-sixth the non-paying weight.

Some persons may take exception to the rating of the assumed items, but, even should they be found strained or faulty, which I have taken all pains to prevent, the amount of their error, however largely it may be estimated, cannot materially affect the issues.

Weight of the average goods train was, in 1867—

Non-paying load, viz:		
Engine and tender..........	50 tons.	
Two breaks................	8 "	
Six goods trucks at $3\frac{1}{2}$ tons each, to carry 3 tons......	21 "	
Six mineral trucks at $3\frac{1}{2}$ tons each, to carry 7 tons each..	21 "	
		100 tons.
Of the above, to be sent back as empties, two goods trucks six mineral trucks........	28 tons.	
One-fourth engine and tender, with empties.............	12 "	
		40 "
Paying load.		
Goods	19 tons.	
Minerals	41 "	
Six and a-half head live stock	1 "	
		61 "
Total		201 "

In this table the detail of the item 61 tons is taken from the Board of Trade returns; the other items are assumptive (under certain restrictions, which will be apparent), still not to be omitted. These two tables give the average weights of the passenger and goods trains of the year; by multiplying their several sums by the total numbers of trains, passengers and goods respectively, run in the year, as given in the returns, I have arrived at the great totals given before.

The second point to which I have asked your attention is that of the immense excess of the non-paying weight of the trains over and above the paying weight. This is a subject which is frequently treated in the scientific publications of the day, and which has been discussed at meetings of this Society, but I am not aware that it has been hitherto considered in connection with the Board of Trade returns. In the annual address, which I had the honor to give to this Society in October, 1868, I alluded to the subject of non-paying weight. I then gave an estimate of what I believed to be the proportions in which these two divisions of the total weight of the train are to be found. The non-paying weight, large as it was, I now find was understated, as shown by the astounding results extracted from the returns. This was in part owing to the fact that the figures were drawn from a much smaller railway circle than that from which the returns immediately before us have been computed.

The proportions of the paying weights of trains run in 1867 were, viz:

Passenger trains.
Paying weight, 4.89 per cent of the total weight of the train.

Goods trains.
Paying weight, 30.34 per cent of the total weight of the train.

Total Passenger and Goods trains.
Paying weight, 16.67 per cent of the weight of the whole train.

Or, in simpler phraseology, it takes 19 tons of train equipment to carry one ton of passengers, 2¼ tons of the same to carry one ton of goods, and, in gross, 5 tons of equipment to carry one ton of paying load.

That the public are not acquainted with these facts is, I believe, the secret of their discontent with the management of our railways. They place themselves willingly under the direction of theorists, who are not competent to realize the situation. Relieve them from this state of suspense in which they are placed, make them familiar with the reason why they cannot hope for a reduction of fares, and they will rest content, and railway property cannot fail to be the gainer thereby. Show them that the experience of the Post-office cannot be taken as a guide for the management of railways, because a letter weighs practically nothing, as I have endeavored to show in the address before mentioned, and that its numbers may be increased almost indefinitely without extra cost of carriage, whereas a passenger will weigh two tons, including his share of train equipment; and, moreover, that each passenger carried, in addition to the usual numbers, will bring an additional weight of two tons with him. Show them that the fares charged by excursion trains cannot be taken as a guide, because the conditions under which they are run are not those required in the conduct of the common traffic trains of the country. Show them that the extremely low fares charged on the Belgian railways cannot be taken as a guide, because, firstly, what are commonly called the Belgian railways, and notably so in the second report of the Railway Commission of 1868, are not the Belgian railways, but only a fraction of them, that is to say, 535 miles out of 1,819; secondly, that they were constructed by the Government, before private railway enterprise had commenced in Belgium, who naturally selected the most promising lines of country, and are, in fact, possessed of the cream of the traffic of the land; thirdly, that these lines have cost £18,000 a mile as against £36,000 for the English lines; fourthly, that these lines have been charged with no parliamentary expenses; fifthly, that land is of far greater value in England than in Belgium; sixthly, that labor is dearer in England; seventhly, that the speed of the Belgian trains is considerably less than that usual in England. That all these things combine to make the working of railways more costly at home, and so to produce higher tariffs of fares and rates; and, finally, that no later than this month, M. Malou, Belgian senator, and well versed in the railways of that country, has shown, in a pamphlet which he has published, that the glowing promise of a new railway era, to be inaugurated by these gifted Belgian legislators, is only a juggle and a delusion, and that the Government must immediately raise their fares considerably, unless they are prepared to work their 535 miles of line, having cost £10,000,000, with an utter disregard of the ordinary principles of economy and trade, and at an enormous loss per annum. Lay all these facts and views of the question before the traveling public of England, and they will quickly wipe the film from off their eyes that now rests there, and be led to confess that, after all, the men who have invented and perfected the locomotive and the railway, with its belongings, and instructed the world in the art of working and using it, are as likely to know how to tend, and direct, and manipulate it with skill and sagacity, as are their continental and other pupils.

The English engineer knows that natural

and economic laws must eventually prevail, no matter how the public may wish to dispense with their action; he knows the ways, paths, and tendencies of these laws; he knows how to respect them, as respected they will be; while he also knows how to bend them to his educated will. With these laws as his guides, and with the forces which nature permits him to wield as implements, he goes on in a safe and sure road of progress, and, as he advances, hardly turns his head to reply to the dreamers and triflers, who preach from the stump and the journal the reversal of the order of nature.

This immense dead or non-paying weight has ever been a difficulty with the engineer. Dead weight has no doubt increased of late—engines are made heavier, hence more adhesion, less liability to become derailed, and greater economy of fuel in working; carriages are made longer, hence there is more space for the legs of passengers; they are made higher, hence more facility for moving when in an erect position; the timber is of large scantling, hence more steadiness and durability—all these changes have been changes for the better, the traveler, in consequence, is more convenienced as well as physically safer than before—the latter a boon that cannot be over-estimated; he is actually 1,000 per cent safer at present sitting in a railway carriage in motion, than when walking in the London streets. The Briton of the age, in short, travels fast and securely; faster, indeed, than the representative individual of any other nation; he is in the condition of the man who lives fast, and builds a large and comfortable mansion for his gratification; its dimensions are greater than are absolutely necessary for his wants, yet he can afford the cost and he defrays it. The Briton must do likewise if he wishes to travel fast.

Reduction of non-paying weight is practicable, but it implies a reduction both of the rate of speed and of convenience, and it is not likely that it can be attempted in the face of the long enjoyment of these luxuries which the public have possessed. The receipts per mile from the 73¼ persons who traveled per train run in 1867, were, viz:

	Persons.		s. d.	Corrected income per mile.
1st class......	8¼	at 2d. per mile,	1 4¼	1 2¾
2d class......	20	at 1½d. "	2 6	2 3
3d class......	45	at 1d. "	3 9	3 8
	73¼		7 7¼	7 1¾

The column headed "Corrected" shows the correct figures, having made the proper deductions because of return tickets, which may be taken at 60 per cent of the whole number of tickets issued for 1st and 2d classes. This 7s. 1¾d. per mile must not be confused with the 4s. 9d. per train mile of the returns; the first is the income per mile run by the 73¼ passengers, the average mileage run by each passenger being 12¾ miles, while the average mileage per train was 19 miles.

The following details may be useful, viz: 73¼ passengers carried in each of the 3,924,-624 passenger trains run. Paying and non-paying weights of each train 143 tons, being a total weight per passenger of two tons. Total weight of train per one ton of passengers equal to 20 tons 8 cwt. 60 tons goods and minerals, and 6½ head of live stock carried in each of the 2,403,866 goods trains run, paying and non-paying weights of each train 201 tons, being a total weight per one ton of freight of 3¼ tons.

Each passenger train, weighing a total of 143 tons, was pulled over a distance of 19.-08 miles, bringing a revenue of £4 11s. 4¾d., equal to

	d.
Per mile ton of paying weight..............	8.2
Per mile ton of total weight of train.........	.40

Each goods train, weighing a total of 201 tons, was pulled over a distance of 30.64 miles, bringing a revenue of £8 19s. 2¾d. equal to

	d.
Per mile ton of paying weight	1.14
Per mile ton of total weight of train.........	.34
Passengers revenue per head per train mile..	.78
Passengers revenue per head per mile actually run by each passenger..................	1.17

These figures lead to the vexed question, viz: the relative paying properties of passengers and goods, which is shown in the items, as above, viz:

	d.
Passenger revenue per mile ton of total weight of train..................................	.40
Goods revenue per mile ton of total weight of train	.34

These figures are not strictly accurate, while sufficiently so for our purpose, because we know from the passenger revenue per head per train mile of .78d., that each passenger cannot have traveled the whole 19.08 miles run by the passenger train. I find that the actual distance run by each passenger was about 12¾ miles, or three-quarters more than the distance run in 1855, as given by

Mr. Robert Stephenson in his address to the Institute, in 1856, before alluded to. The precise distance run by each ton of goods pulled is not so easily found. However, all things considered, the deductions for these drawbacks of passenger and goods mileage from the 19 miles and 30¾ miles run, will not cause any material error in the representative fractions .40d. and .34d., the incomes per horiz. mile ton, respectively, as the deductions would only apply to the paying weight sections of the train, which in each case is small as compared with the total weights.

These fractional figures would place the advantage on the side of passenger traffic to the extent of .06d. per horiz. mile ton, but against such is to be placed the serious debit of 90 per cent more speed, also 90 per cent more of capital invested in vehicles, valuing carriages at £200, and trucks at £60 each, the capital invested in the latter being, viz:

Carriage capital, per ton of freight pulled per annum .... 3s. 9d.
Truck capital, per ton of freight pulled per annum .... 2s. 0d.

While to its credit is to be placed, say, 50 per cent less concussion, and the carrying of 75 per cent more freight per vehicle, etc., viz:

27,354 carriages carried 27,472,368 tons, or 1,004 tons per vehicle.
247,048 trucks carried 146,635,826 tons, or 593 tons per vehicle.

A debtor and creditor account would stand thus—

PASSENGER TRAFFIC,
AS AGAINST
Dr. GOODS TRAFFIC. *Cr.*

90 per cent more speed.	17 per cent more revenue per mile ton of total weight pulled.
90 per cent more vehicle capital invested per 1 ton of paying load pulled.	50 per cent less concussion, viz: load carried 12 cwt per foot of wheel base, as against 20 cwt. to 40 cwt.
	75 per cent more paying load carried per vehicle per annum.
	12 per cent greater facility in reception and delivery of paying load.

I shall not now strike the balance; the advantage, however, at first sight, is on the side of goods traffic. If the two sides should be found on a line, it will be a remarkable proof of the sagacity of railway managers, in that they succeed in making the two great divisions of traffic revenue contribute equally to the general account.

I must not forget to acknowledge my obligations to Mr. Frederick T. Haggard, of Burnham House, Kent, for the assistance which I have received from him while investigating this question, as well as for the hints which I have taken from his valuable pamphlet, entitled "A Mile of Railway," published last February.

The moral which I have endeavored to make this paper convey, is this: that so long as the railways of the United Kingdom shall carry passengers and their train equipage at .40d., or two-fifths of a penny, per ton per mile, at an average speed, while running, of 34 miles per hour, and goods and minerals, with their accompanying dead weights, at .34d., or one-third of a penny per ton per mile, at a speed of 18 miles per hour, the public cannot complain.

If they will take a common sense view of the question, and compare these rates and speeds with those of such other modes of traction as they are familiar with, and further, compare them with those of other countries, giving their own country credit for the many and great conveniences and accommodations which the system confers upon them, as well as taking due cognizance of the quality and price of the material out of which the fabric is made, and upon which it is built up, I feel assured their verdict will agree with that before quoted—that in the matter of railways they are "the best served community in the world." These returns disclose the strange facts that the average British passenger weighs two tons, with train accessories, and that the ton of goods, etc., weighs 3¾ tons; by no known processes can these enormous multiplication of original net weights be reduced, consistent with affording that amount of personal security, and comfort, and accommodation now enjoyed; let them, in their future deliberations on this subject, relinquish the idea which has so long clung to them, and which has been so ingeniously and persistently placed before them, that a railway passenger is a featherweight—a letter or a newspaper, as it were—and that he may be treated accordingly, let them try to realize the facts as stated, as to the actual total of paying and non-paying weights pulled, and the enormous energy developed in order to produce the effect expressed in the figures as before given, viz: 25,512,646,408 horiz. mile tons.

These, combined with the figures representing the wear and tear of material, and the labor expended in the maintenance of the system, will, perhaps, convince them of what an exacting, devouring, and insatiable monster it is that they have called upon to minister to their lately-born wants, and will go far to reconcile them to the existing tariffs of fares and rates, which, no doubt, competition and the wish to act in a just and liberal spirit to all parties concerned, on the part of railway executives, has already reduced to the lowest admissible rate. I believe that these are amongst the "things not generally known," and that when generally known they must tend to promote and strengthen that cordial understanding which ought to exist between the railway proprietor and the traveler by railway, and so without fail to increase the confidence of the investing public in this great property, and as a necessary sequence, to enhance its money value.

THE FAIRLIE STEAM CARRIAGE.

From the "Mechanics' Magazine."

The name of Mr. Robert F. Fairlie has, for some time past, been brought prominently before the public in connection with the economical working of railways. The Fairlie engine is well known to our readers, and a brief description of his steam carriage has also appeared in our pages. A trial of this carriage was made July 15th, at the Hatcham Iron Works, which successfully demonstrated the practicability of working the system upon railways, with curves of only 50 ft. radius. The steam carriage exhibited, and which was not quite completed, was designed to work on a metropolitan railway, at the terminal stations of which sufficient space could not be given for laying down rails on a curve of 25 ft. radius for the standard carriage to run itself round; consequently, the standard carriage had to be altered in dimensions to allow of its being turned on an ordinary 40 ft. turn-table. Hence, instead of seating, as is intended, the 100 passengers in the standard carriage, the carriage under trial only gave seating space for sixteen first class and fifty second class, in all sixty-six passengers. The accommodation per passenger is as good as is given on the best lines, and infinitely superior to the stock usually worked on branch lines. The length of the carriage is 43 ft., including a compartment near the engine for the guard. The engine, carriage, and framing all complete, in working order, but exclusive of passengers, weighs under $13\frac{1}{2}$ tons, and including its full load of passengers, $18\frac{1}{2}$ tons only. The carriage when finished complete will have a broad step or platform on each side, extending its entire length; this step is protected by a hand rail on the outside, with an arrangement for lifting it on the platform side at the doors to allow the passengers to get in and out. The object of this platform is to enable the guard to pass completely round the train at all times, and while doing so, he is perfectly safe from any accident. Passengers can also pass along the platform to the guard, so that in this manner there is an easy and perfect mode of communication between passengers and guard.

It is intended, however, in the standard steam carriage to provide a central passage inside the entire length of the carriage, leading direct from and to the guard's compartment; thus there is the most direct means of communication between the passengers and guard. The compartments in the carriages will be quite as separate and distinct as they are at present, or as the most fastidious could desire. The guard passes through the carriage at pleasure. Those in the higher classes can pass to the lower, but the lower cannot get to the higher, while all can pass to the guard when required. The standard carriage will have two compartments first class, to seat 16 persons; three compartments second class, to seat 30 persons; and four and a-half compartments, third class, to seat 54 persons—in all, 100 passengers. The machine complete, in working order, will weigh about 14 tons, and with the 100 passengers, from 20 tons to 21 tons. These carriages will convey their full complement of passengers at forty miles per hour up gradients of 1 in 100, and, as demonstrated, will pass round curves of 50 ft. radius at twenty miles an hour with perfect safety.

There are few trains on any of our railways which convey more passengers per mile than can be accommodated by one of these steam carriages. In fact, it is known that the average number of passengers, taken from the Parliamentary returns, give only about eighty passengers conveyed altogether by each passenger train in the United Kingdom, from the time it starts until it completes its journey; and this only gives about an average of 30 to 35 passengers at any one time in the train, for each mile traveled. Of course, there are exceptions to this number on our principal mail lines, but even in these cases, a greater number is the exception, and not the rule. The weight per wheel of the steam carriage being only about $2\frac{1}{2}$ tons, it follows that very light rails may be used, with everything light in proportion. The passage of such sharp curves so easily will enable us to make lines very inexpensively; we need no embankments or cuttings or heavy masonry works of any kind; therefore, lines will be made cheaply and stocked cheaply. Under these circumstances, there is no reason why every village should not have its line either direct or communication with some of the main lines, to which these light railways would act as feeders, and not like the present branch lines, which really act as suckers and not feeders. Many of these branch lines have actually cost a larger sum per mile than the parent line, over which the traffic from the particular branch would not represent more than 5 per cent, if so much, of the total traffic. Then how, in the name of wonder, can such lines pay? When a gentleman desires to open up an estate for building or agricultural purposes, the first thing he considers is the making of suitable roads through it. Now, instead of roads, there is no reason, why these light railways should not be made. In time it will come to this.

We are only, in a sense, beginning railways; we must have double, aye, treble the mileage we have at present, but every one of these miles must not only be constructed but worked in a very different manner to that in which they have been, and are being at present. We have only to consider this simple fact: the steam carriage, with 100 passengers included, weighs about 20 tons, while the tender which accompanies the ordinary locomotive, and which is perfectly useless, except to carry food for the locomotive, weighs as much, if not more. The usual passenger trains average in weight, exclusive of passengers, about 80 tons; therefore, it follows if to work 80 tons it takes 30 lbs. of fuel for the locomotive per mile, to work only 20 tons, one-fourth of the fuel would be required. The reference to fuel means oil, tallow, and every material required to maintain the engine; it means also the same proportionate reduction in the cost of maintenance of permanent way, and all charges connected with the working of railways. The proper method of working railways is to take the largest possible loads, and, consequently, fewer numbers of goods trains; so that instead of earning about 6s. per train per mile at a cost of 50 per cent, netting 3s., these should earn double the amount—say 12s. per mile—while the cost would not exceed 1s. over the 3s. spent to earn the 6s., giving a net production of 8s., instead of 3s., or about 280 per cent more.

Then, again, the passenger trains which now earn under 5s. per train per mile, and costing 50 per cent of the amount, or 2s. 6d. to earn it, could be worked with the steam carriages at a cost of about 1s. 6d. per mile, thus adding 40 per cent to the net receipts on passenger traffic. It is to be remembered that these percentages are pure gains to railway companies, the cost of management and other charges being taken as remaining the same, the profits arising solely from the improved mode of working. The Fairlie engine can haul double the ordinary loads of goods per train, without injuring the permanent way so much as is now done by the ordinary engine; and allowing for the increase in the consumption of fuel for the load taken, all other expenses remaining the same, the extra cost on each could not exceed even 6d., although 1s. is placed against this item—therefore, the profit must certainly be very great.

While on the subject, we now notice the Fairlie engine "Little Wonder," which has been built for the Festiniog Railway Company, and which has obtained very considerable notoriety from its being the narrowest gauge passenger railway worked by locomotives in existence. The line has been worked now about five years, and during that time there has not been the slightest accident of any kind; in fact, it is considered a most extraordinary line, not only on account of its gauge, which is only 2 ft., but because of its success commercially. The traffic hauled last year over this miniature line of twelve miles in length amounted to 130,000 tons of goods, and 145,000 passengers, which would be considered a very handsome traffic for a full-sized railway of the same length, and the wonder is, how it has been done. The credit is due to the able management of Mr. C. E. Spooner, managing director and engineer. The traffic has so increased that the ordinary engines are getting too small to pull the loads, and hence the adoption of the Fairlie engine, which at once enables the train loads to be doubled, without, but in a very small degree, increasing the cost of each train. The Festiniog line is, for about eleven miles, one continuous ascent of about 1 in 80, with very many curves, some of which are as small as 100 ft. radius. The "Little Wonder," although weighing but 19½ tons, fully equipped with fuel and water for the road, will haul after it 140 tons, at a speed of fifteen miles an hour for the whole eleven miles; a feat, considering the gauge and weight, that could not be accomplished by other than the Fairlie engine. The engine has eight wheels, in two separate groups of four each, each group being acted on by a pair of cylinders 8½ in. diameter. The wheels in each group are 2 ft. 4 in. diam., and are coupled together.

The extreme wheel base is 18 ft.; consequently, the engine will run with remarkable smoothness. At the same time, the wheel base of each bogie being but 5 ft., the engine will pass round curves of 50 ft. with the utmost safety at 20 miles an hour. The principle in this respect is precisely similar to that of the steam carriage passing curves of 50 ft. The fact of either steam carriages or engines being constructed to run with perfect safety round curves of 50 ft. is unprecedented in the history of railways, and places the railway world under a considerable obligation to Mr. Fairlie, who has spared no pains to perfect a system to which we wish every success.

ACCUMULATED HYDRAULIC POWER.

From "The Engineer."

The advantages in economy and convenience which attend the use, for many purposes, of accumulated power, are by no means generally understood. By accumulated power we mean power which is generated continuously, to be used at intervals without any change in the application, such as occurs in the use of a hammer, where the accumulated power is used percussively. In this case there is such a sudden application of the accumulated power as to cause very marked differences in effect from the effect of the same, were power applied in any other way; in fact, it is well known that for certain purposes it is imperative to apply power percussively; but the purpose of the present article is to deal exclusively with the question of the periodic use of continuous power as affecting the economy and convenience of machines used for manufacturing purposes. Power may be accumulated in very various ways, but it is in the hydraulic accumulator that we find the most extensive and convenient application of the principle. To the application of hydraulic accumulation we shall therefore confine our attention, and, further, we must premise that direct applications of hydraulic power, as in the hydraulic jack, do not bear upon the question, as we have in all such cases a concentration of the power, it is true, but no accumulation.

Five points have to be considered in relation to the subject in hand, namely—(1), the cost of generating the power; (2), the loss by friction; (3), the cost of the machinery; (4), convenience of application; and (5), the cost of maintenance.

The cost of generating the power should be taken as including all expenses incurred in the prime mover and the pumps and accumulator, as the power developed by the prime mover is, till transferred to the accumulators, of no more avail than if none existed. Very erroneous statements have been put forward as to the cost of pumping into accumulators, such statements being usually based on the duty performed by pumps working at lower pressures, such as are required for work of a totally different kind. The friction in pumps working at low pressures very much exceeds in proportion that of hydraulic pumps working at high pressures, and we shall be able to show that the percentage of friction rather diminishes than increases with the pressure, even at high pressures. Further, the amount of power accumulated will increase as the differences of the squares of the diameters of the plungers, but the friction of the plungers only increases as the first power of the differences of their diameters. On this ground, pumps of large diameter and short stroke seem most desirable, but the frequent opening and closing of the valves, and the greater strength of the framing and gearing required with such increase of diameter, must be weighed in practice, and a line drawn beyond which this theory must not be pushed. The increase of friction from the increased strength of gearing cannot be stated otherwise than by a reference to each particular case, but a little consideration will make it evident that this increase bears but a small proportion to the diminution of the friction on the plungers, because the speed of the moving parts is in the inverse ratio of the squares of the diameters of the plungers, while the increase of the frictional surface will be in the direct ratio of the diameters. It may be taken roughly that the increase of friction in the gearing will be directly as the increase in the diameter of the plunger, and the diminution in the friction of the plunger in a like proportion. There is one other element of friction to be considered ere the power accumulated is available for use, namely, that due to the passage of the water through the pipes, forming the communication between the accumulator and the machines which use the power. This friction is but little increased by the length of such pipes, but is very seriously augmented by all indirect-passaged valves, sudden bends, and all alterations of the form or area of passage. Of these and other kindred points we shall speak more fully in future articles when we come to discuss the designing and making of hydraulic apparatus. Having reviewed these preliminary points, we can now pass to the consideration of the great source of economy incidental to the use of accumulated power for intermittent work, such as punching, shearing, forging by dies, bending and straightening metals, hoisting, pressing and packing, and many other processes. The chief source of economy lies in the use of a far smaller prime mover than could otherwise be used, such prime mover working against a continuous and equal load, and therefore, *cæteris paribus*, working economically. Fully to appreciate this advantage it is necessary to bear in mind, that the saving in the size of the prime mover is in direct proportion as the intervals of rest of the machines exceed their intervals of work, and is at a maximum when the work is regularly intermittent, and of the shortest duration as compared with the intervening period. It naturally follows, therefore, that heavy work requiring some time for its intermediate handling and preparation, followed by the exertion of excessive pressure through a small range, offers the most economical field for accumulated power. As the intervals of rest grow shorter the economy diminishes, but not necessarily the convenience. To make our meaning plainer, let us take the case of shearing and punching plates, requiring, say, fifty-four seconds each to place in the tools, and the application of a power for six seconds equivalent to raising 500 tons through 1.2 in. In round numbers, 34-horse power will be the power developed for six seconds. Now, supposing a water-wheel or steam engine to be the prime mover used, we should require one of 34-horse power continually at work, during only one-tenth of which time would it do any useful work; with an accumulator, on the other hand, one of 3.4-horse power would do the work. It will be seen, therefore, that we save the power absolutely lost in driving the larger engine or wheel for nine-tenths of its time, the interest on its first cost, and the extra room it would require. In each case, to a small engine or other prime-mover, pumps of equally small size will be required, but the size of the accumulator depends on other data. By the following method the proportionate sizes of each part of the hydraulic apparatus may be fixed: The work to be done in, say, one hour or one day, must be estimated; then a prime-mover must be fixed upon capable of doing this work per hour or per day, and, as before stated, the size of the prime-mover will indicate the capacity of the pumps. The capacity of the accumulator must be arrived at by estimating the duration of the longest interval of rest, and then calculating the size of the accumulator to hold the full quantity pumped during that time. After the capacity of the accumulator has been arrived at, it will be necessary to determine what length of stroke shall be adopted. This will involve important practical considerations regarding the load to be carried, and its momentum in falling when water is drawn by the machines. The power remaining the same, the pressure per inch will exercise a considerable control as the designing of the pumps and accumulator. We shall defer treating these points in detail, as our space will not, in the present article, admit of more than a general treatment. We now come to a very important point in the use of hydraulic machinery, namely, the cost of machines themselves and their size. In the first place, we note that well-designed hydraulic machinery for the various operations before mentioned is very simple in its constructive details as compared with geared machinery, is also much smaller and lighter than other machinery of equivalent power, and exhibits a much lower percentage of friction. It is also a fact that as the power is increased, these three advantages of simplicity, lightness, and small frictional cœfficients, become more and more marked as compared with other contrivances of corresponding power. Of course, cost in machinery is considerably dependent on simplicity of parts, and it will be found that in all cases where hydraulic machines have been properly designed and made, the first cost and the cost of maintenance have been small, compared with other machinery of equal capacity. The chief item of expense in the maintenance of hydraulic machinery lies in the cost of renewing the cupped leathers; and from want of a little good bainwork in the design of the machine, the cost of putting in the latter is often far more than the cost of the leather itself—in fact, it is the writer's experience that this is the rule rather than the exception. It is also very noticeable in most cases that the leathers do not have a fair chance of a long "life" by reason of the inferiority of the surface against which they work, arising from "specks" and deficiency of finish. It is very difficult, nay, even impossible, to get a perfectly clear surface on cast or wrought iron by ordinary tools and operations; but much may be done by the adoption of little practical "dodges," of which we shall have occasion to speak hereafter. The consideration of the convenience of hydraulic machinery opens up a very wide and interesting field of applied mechanics; but one rather difficult to treat of generally, as each individual case offers some distinctive features of its own. Yet we can select certain salient features which may serve as mental standpoints from which to regard isolated cases, which may arise in each branch of manufacture. In all cases where it is a necessary part of a process to have a machine to stand for accurate adjustment of the work, as in punching, shearing, etc., accumulated hydraulic power is very advantageous, as the tools can be brought close to the work and kept at any point quite steady till the adjustment is complete, when the blow can instantly be obtained. There is also the very great advantage that the pressure can be kept equally on the work, aud will follow it up self-acting, which other gearing will not do satisfactorily. There is one point of superiority in hydraulic pressure from an accumulator which in many operations is eminently important, and which is equally characteristic of it, and that is, that if the "work" will not yield, there is not an increase of pressure, as in other cases, and therefore no risk of such an increase of strain as to break the machine. No doubt many of our readers have seen numerous cases, in machines which possess momentum and have to pass a dead center, of ruinous fractures, due to some impediment which has got in and tended to stop the machine. In such a case there is an instantaneous conversion of the *vis viva* of the machine into a force which often becomes disruptive. As an instance, the fractures of screw-heading machines may be taken; nor are such instances uncommon in ordinary shearing machines. There is no remedy for this difficulty other than to adjust the strength of the machine so as to be capable of suddenly absorbing the *vis viva* of its own moving parts. This, however, cannot always be done. Hydraulic machines, on the other hand, require only to be constructed capable of bearing the normal strain of the work, as such strain cannot, in the very nature of the case, become abnormal. In all cases where a large power is required to be put on a small area, hydraulic power offers great advantages, as small, accessible, and easily controllable tools of immense power can thus be obtained; but in some cases peculiarities in the work modify these advantages so far as to preclude this successful application, as for instance, where it is imperative to have a long traverse with very little work except at the end of the stroke. In such a case the great waste of power would preclude such an arrangement, except in cases where convenience was a paramount question and power of little value. It is in dealing successfully with such questions of suitability that the engineer can show his grasp of his profession, and on such fields do the masters of the credit meet and overthrow the mere charlatans and men of a "groove."

EXPLOSIONS OF NITRO-GLYCERINE.

From "The Engineer."

After referring to the late disaster in Wales, our authority proceeds as follows: Our object is not now to discuss the unfruitful question of what brought about this disaster, as its proximate and immediate cause, but to offer a few practical remarks with a view to prevent the recurrence of others, based on a somewhat more precise knowledge of the properties of the substances concerned than appears possessed by the "correspondents" of our various contemporaries, or by anything brought before the "crowner."

Since the introduction of nitro-glycerine to practical use, at least half a dozen tremendous explosions of it have taken place in Great Britain, several in America, and a few in Germany and France. Their effects in destroying life—with circumstances as sudden and inevitable, and more appalling than death by lightning—have filled the imagination of all who have listened to or read accounts of them with inexpressible dread of this tremendous agent; and it is quite likely that at the motion of some of our legislative wise men—of the kidney of those who would abolish patents because they hamper some people and tend to produce lawsuits—some attempt will be made to interdict the use of nitro-glycerine as a blasting agent in our country; or so to restrict the conditions for its storage and transport as to diminish, or even neutralize, its enormous advantages to the quarryman, the miner, and the tunnel-driver.

We do not for a moment contend that some legal and police regulations as to its manipulation in storage and transport are not most desirable; on the contrary, we say at once, the necessary powers for *codifying* and rendering such stringently operative ought to be taken, and immediately applied. But let us first clearly ascertain what such regulations should consist in, and how far they need go.

If nitro-glycerine, like tri-nitro-cellulose or gun-cotton, be badly prepared—we shall not here go into any chemical particulars—it may pass into a state of incipient decomposition, and of chemical condition so unstable as to explode—as we may popularly, but still not with philosophic accuracy express it—spontaneously.

Against this the only real safeguard must be the skill, fidelity, and reputation of the manufacturer; and were proper means taken to prevent extraneous and other causes of explosion, the makers of nitro-glycerine would see that it was to their own interest to send out nothing but such as was, in this respect at least, safe. In fact, we have no doubt that, as far as any tendency to explosion of this sort goes, as much may be done for nitro-glycerine as Mr. Abel—following after Von Lenck and others—has done for gun-cotton, which once had, and somewhat justly, a bad character in this respect.

But, secondly, let us ask, on behalf of nitro-glycerine, is it to be supposed that more than seven hundred years ago—when gunpowder first began to be practically employed as an explosive agaent—that there were not many and terrible so-called accidents attending its use? Such must be the course of events with any new and powerful agent suddenly brought into popular handling; and such must equally tend to disappear as popular ignorance gradually gives way to rapidly diffused information as to the properties of the newly-acquired agent. Well, what remains, then? That we can and ought so to guard against, as serpents, the properties of this new agent, so enormously more powerful when exploded—and as exploding by concussion, so unquestionably more dangerous than gunpowder.

To say in sufficient detail all we could say, and at the proper place, should be prepared to say on this, would far outstep the limits of a leading article, but it may be all condensed into one general sentence—so store and so transport your nitro-glycerine that concussion or percussion, internal or external, shall become physically impossible, and so that no violent or extreme change of temperature, above or *below* a fixed mean, shall occur; effect that, and future danger or "accident" will, to a great extent, vanish.

It seems but little generally known that the wonderful, and even yet little understood rapid inversion of chemical forces called explosion, tends to propagate itself, by mere shock perhaps, from one isolated mass to another. The facts observed as to the successive blowing up of more or less distant buildings in powder mills, when one only has been first exploded, shows that this is true even of gunpowder, an agent which is with great difficulty, and only under certain circumstances, caused to explode by percussion, as Faraday long ago showed. But it is eminently true of fulminates properly so called, of which nitro-glycerine is one; for though explodable either by sufficient ignition or heating, it is far more readily so by any violent shock, or by a blow from a hard body, or from even a gas evolved at great velocity, as from a percussion cap.

When Mr. Hennel, the operative chemist at Apothecaries Hall, London, was blown to atoms many years ago by the explosion of a large copper dishful of fulminate of mercury, holding several pounds, beside which at a distance of several feet he was standing, the explosion of the whole appeared to have been induced by the slight but sharp impulse given through the air, by the explosion of a grain or two of the fulminate which he incautiously took out and exploded by a blow of a hammer to judge of the quality of the mass itself.

Mere subdivision of nitro-glycerine into small parcels—these being placed tolerably adjacent or in the same building—will be nugatory as any safeguard that one portion only may explode and leave the others untouched.

Roughly we may say that unless the distance between the stored separate masses be such, or the interposed divisions—such as heavy walls, vault arches, or the like—be so massive that the shock or sound of the explosion of one mass shall be imperceptible at any one of the others, mere subdivision can afford no certain security that when one goes all shall go off in succession. But there is another circumstance to be taken into account—the effects. Now, the leveling agency and life-destroying power of nitro-glycerine are so great, and so much in excess of gunpowder, that subdivision ought to be insisted on, and we hold it that the law should provide:

1. That no nitro-glycerine should be stored at all, except in places not less than half a mile from any inhabited house or factory, or other usual resort of large numbers of employed persons.

2. That public stores should be provided for it, to which it should be removed from ship or railway on the night after its arrival, and only at night.

3. That not more than 500 lbs. should be stored any-where in one mass, and to that extent only in public magazines.

4. That transport through public thoroughfares should only be done on license given, after written notice to a public officer (probably of the customs or excise), and then accompanied by a subordinate appointed by that officer.

5. That all private consumers should be obliged to provide magazines, to the approval of a recognized authority; and that these be on the same principle of distant subdivision and position as to human habitations, etc., as the public magazines; and that the maximum stock in any one mass should not exceed such quantity less than 500 lbs., as such authority should sanction.

These regulations would really impose no serious burden or restriction to use, and, so far, would be pretty effectual.

There remains, then, the mode of package and transport; and here there is immense present recklessness, and room for an immense improvement. Soldered zinc or tin-plate or galvanized iron bung-stopped cans are about as dangerous as any vessels can be. Leakage can scarcely be avoided at the bung—a screwed stopper is still worse—the chance of leakage is great, and a fragment of flint, or grit, or glass, or of any hard body, in extracting or replacing it, may cause explosion. The soldering is often staunch at first, simply by reason of a film of *rosin* at an imperfect place; and when this dissolves or is rubbed away leakage occurs; and if some of the leaked liquid be exploded, though outside and some feet, perhaps, from the can, the whole may explode. But there is a further and more insidious cause of danger. Many such cans have bits of loose solder accidentally included in them, or bits that may become loose. These are necessarily tail-like bits, with sharp points and of angular forms. These, if shaken about in the can, may induce explosion, as may a bit of wire, or an iron prong or broken corkscrew, or any sharp and hard solid if dropped into the can, and afterwards shaken about in it. In fact, just as a needle thrust into a glass of still soda-water or a few angular crumbs thrown into a glass of dead champagne will re-establish effervescence, so is the instability of already unstable chemical compounds increased, and if explosive, their tendency to explode. Even rough points, or lines, or seams, and far more, sharp corners or re-entering angles in the inside of vessels have the same effect, of which many remarkable examples have been noticed and recorded, both as regards combination and decomposition, by Chevreul, Becquerel, Mallet, and others. But we must be brief. We say, therefore, that in place of these cans the only vessels permitted for transport and storage of nitro-glycerine should be strong ellipsoidal metallic bottles, something the shape of a soda water bottle but of larger diameter in proportion to length, and each made out of one sheet of metal without solder or seam, by the method of hydraulic pressure in suitable moulds, which was exhibited, in 1867, in the French department, and examples of its marvelous facility and adaptability to any form or size there shown.

These vessels should be strong enough to resist dinges or dents by any moderate blow or by being let fall from a man's hands, and should be perfectly smooth within. The neck should be wide enough to enable the whole inside to be examined by the aid of a properly projected and powerful illumination, and it should be closed neither by bung nor ground valve, nor screw cap, nor by anything capable of producing rubbing, friction or catching up grit, or requiring force and iron instruments to extract—but instead by a flat plate having a ring of gutta percha or cork, or other more suitable and slightly compressible material inserted flush in a circular sunk race, and made to bear against the flat edge of the neck of the vessel. This plate or valve should be pressed tight into place, and held there by a screw bearing upon its outer surface, and passing through a ∩-shaped bridge, hooked on to two lugs, formed outside the neck of the bottle. Each such bottle should be packed into a sheet iron cylindrical canister with a cap, and at least 2-in. or 3-in. of dry elastic sawdust intervening all round it, and each such packed canister should be enveloped always in a thick mat of "gunny bagging," or other cheap elastic material.

We cannot extend here further, though much more remains that we should like to add. However, were even the precautions, which we have here rapidly sketched, taken, and zealously, and not in laziness and official sham, but really carried out, we venture to affirm that a considerably increased length of time would be found to elapse before the next blow-up of nitro-glycerine should occur; and whenever it should we would hope that the coroner's jury verdict would not be, as at Carnarvon, one of "accidental death."

SHRAPNELL *v.* SEGMENT SHELL.

From the London "Times."

There are three distinct parties in this controversy. First, the out-and-out Segmentite, who considers shrapnel a thing of the past, and has not the slightest faith in it either as a shell or a shot; second, the rabid Shrapnelite, who looks upon his favorite projectile with the fluttering affection with which a hen regards her one chicken; and considers that segment shell violates every condition of scientific and practical gunnery, and is utterly inadmissible in consequence; third, the dispassionate party, who are platonic enough to view the contest with unruffled equanimity, and whose chief object is to get the best thing they can for the service, irrespective of the fact that it is the invention of Boxer or Armstrong. Let us see, now, what these several cliques have to say for themselves.

The Segmentite usually affects to be eminently practical; he disbelieves in the efficient boring of time fuses in action, ridicules the firing of such projectiles under most of the circumstances met with in actual war, and calls the rifled shrapnel a wooden-headed piece of complication. It is absurd, he urges, to suppose that future battles will be fought over ground selected expressly to develop the merits of shrapnel fire. Troops will be more or less protected, the soldier will instinctively seek cover, and the very key of the position on many a battle field may be a rude house and garden, with a few hastily thrown up entrenchments, against which the fire of shrapnel would be entirely thrown away. What would be the position of a general under such circumstances if provided with a shrapnel alone? Must he wait for his siege train before he could attack a farm-house? With what projectile are we to attack stockades, abattis, houses, villages, woods, field earthworks, and war material such as guns, carriages, and wagons? Are horse artillery when acting with cavalry in pursuit of an enemy to be obliged to bore and fix fuses in the hurry and excitement of action, when time is of the greatest possible consequence? Is the No. 1 supposed to ride with his pockets full of fuses, and the gimlet in his mouth? Suppose the man with the bradawl is killed, who is then to "look for the needle in the bundle of straw?" The segment shell can be fitted with a concussion fuse and carried into action ready loaded. No boring and fixing of fuses is necessary. The gun may be served as quickly as with shot; the burst on graze facilitates the estimation of distance, and a few turns of the elevating screw is all that is required. Look at the simplification of drill under these circumstances. The soldier has nothing to look for but the cartridge and shot; he may be the veriest tyro, and still be an efficient gunner. The use of time fuses, on the contrary, necessitates careful drilling. A man whose fingers are all thumbs from the cold of Canada would make a sorry exhibition in boring a time fuse, particularly if he had only been partially instructed, and in case of war there is little or no time in which to instruct the recruits sent out hurriedly to replace casualties in the ranks. Such we may suppose to be the chief arguments advanced by the out-and-out Segmentite.

To him the rabid Shrapnelite replies: The shrapnel shell is constructed on true principles, which cannot be said for the segment. Such a fire is more independent of a correct knowledge of range and configuration of ground than any other. It is manifest that it matters not to the shrapnel shell, bursting as it does in the air, whether the ground be hard or soft, smooth or broken, undulating or flat. The action of the concussion segment depends, on the contrary, on the nature of the particular spot struck. If that be the side of a hill, the projectile enters the ground, and the effect is merely a shower of earth; if it be a soft morass, the shot buries itself in the spongy ground. To obtain good results from segments it is necessary to burst the shell close to the object, and there is a greater chance or probability of oversight in the correct elevation of the gun than there is in the true boring of a fuse where a certain limit of error is admissible. The velocity, again, of the segments will be materially diminished by the shell striking the ground, and the comparative effects will be less than in the case of a projectile bursting in the air unchecked. The spherical bullets of the shrapnel meet with much less resistance from the air than the irregularly formed segments. The fire of shrapnel is much more formidable than segment against troops in the open field, either as skirmishers or in line, and although segment shell may under certain circumstances have a seeming advantage, the result is generally to be attributed to accident. Troops under cover must be dislodged by special means; common shells must be "lobbed" so as to render their retreats untenable. All such defenses as pahs, stockades, abattis, earthworks, etc., must be attacked by common in conjunction with shrapnel shell. The boring and fixing of fuses is a mere matter of drill; in the old smooth-bore days no difficulty was experienced, and there is no evidence to prove that the race of gunners has degenerated, or that we have now less of the coolness and intrepidity for which the regiment has ever been justly celebrated. This soldier-like quality is assuredly present amongst us to-day as formerly. There is no reason why, with an efficient system of drill, shrapnel shell should not be fired just as quickly as shot. It is an error to suppose that heavy infantry or cavalry columns will be massed on future battle-fields; on the contrary, the troops are more likely to be moved in open order, and with an extended formation, to enable them to use with greater effect the improved weapons of the present day. We shall have shallow formations combined with a rapid system of light infantry drill. Against such an order of battle the fire of shrapnel will tell with deadly effect. On the other hand, if concussion fuses are found to be most effective against troops in column, there is nothing to prevent their use with shrapnel shell.

Having heard the arguments on both sides, the moderate party may be supposed to draw the following conclusions: Shrapnel shell, when served with deliberation, is, doubtless more effective than segment shell under certain conditions. On the other hand, the segment shell fitted with a concussion fuse is always ready to hand, and is certainly more simple and decidedly cheaper than shrapnel. Probably two segment shells, with a simple concussion fuse, could be bought at the price of one shrapnel. Again, segment shells, when fired with concussion fuses, have proved themselves very formidable projectiles against abattis, guns, stockades, and troops under the cover of low walls and breastworks. It is very improbable that the leaden bullets of the shrapnel would have much effect in cutting to pieces the wheels of gun carriages or the struts of a stockade. We have fired segment shells with concussion fuses in real warfare, and all the officers who have used them, or witnessed their use, speak most highly in their praise. It is notorious that both the Russians and Prussians look on shrapnel shells with disfavor; even the Austrians, who use a pattern almost identical with our own, are said to have considerably reduced the proportion of shrapnel carried by their field batteries. Now, this course has been adopted, not from the results of a fire against inanimate two-inch wooden planks, but against warm flesh and blood; and, although we may have our insular prejudices on following or regarding the opinion of foreigners, we should proceed with due caution and do nothing hastily. The Boxer shrapnel is an admirable projectile, and we are justly proud of the inventor, but will it satisfy all the requirements of service? If we adopt an exclusive employment of shrapnel, are we right, and all the rest of the world wrong? On the other hand, suppose both are right, would it not be advisable to have some of both projectiles? No doubt by adopting this course we shall please neither the thorough going Segmentite nor the rabid Sprapnelite; but what then? We have no personal interest in either Sir Wm. Armstrong or Colonel Boxer beyond a sincere admiration for the talents of both. Our object is to adopt the best projectile we can for the service, irrespective of its maker. Which would it be best to have—shrapnel, common shell and case; or shrapnel, segment shell and case?

LONDON STREET RAILWAYS.

From a paper before the Inventors Institute by Mr. Thos. Measam, A. I. C. E.

After mentioning the successful attempts of Mr. Train and others to establish street railways in London, and describing the routes of the three roads now projected, in all $6\frac{1}{2}$ miles of double and $6\frac{5}{8}$ miles of single line, the author says: The early tramways appear to have been constructed in the following manner: Cross sleepers of timber, some 6 ft. long, and varying from 6 in. to 8 in. square, were fastened, by treenails or other means, 4 ft. apart. Upon these planks two wrought-iron angle-plates, about 4 in. wide, and $1\frac{1}{4}$ in. thick, were firmly secured. This construction evidently affords all the mechanical advantages that are derived from tramways of more recent date. The tramways laid down by Mr. Train, in 1861, in London and elsewhere, and which were similar in construction to the most improved trams then in use, and which continue largely to be in use in some of the principal cities of the United States, consisted of two wrought-iron plates, each 5 in. wide, weighing 50 lbs. to the yard, and bent at near the center to a depth of $\frac{3}{4}$ in. below the general level of the road. These plates were fixed to longitudinal timbers, embedded on concrete, and the gauge of the line was that of ordinary railways—4 ft. $8\frac{1}{2}$ in. These trams proved dangerous and obstructive. The construction of the improved tramways now proposed is as follows: For single lines of tramway, two flat wrought-iron plates, each $3\frac{1}{2}$ in. wide, weighing 40 lbs. to the yard, with an indented channel $1\frac{1}{8}$ in. wide, and $\frac{3}{4}$ in. deep, placed on one side of the center line of the plates, are to be fixed by bolts, or otherwise, to longitudinal timbers of the width of the plates placed at such distances apart as to give 4 ft. $8\frac{1}{2}$ in. for the gauge of the line. The timbers are to be embedded in concrete 9 in. deep, and are to be of 6 in. or 9 in. in depth, according to the size of the pitching used for the roadway. Tie-bars of thin wrought-iron, connecting the longitudinal timbers, are proposed to be placed at intervals of 4 ft. The space between and on either side of the tramways is to be paved with granite pitching. In the case of double lines, the intermediate way between the trams is to be 4 ft. wide, and the whole space from 11 in. on either side the outside rails, equal to 17 ft. is to be paved the entire width. In other respects the double line is of identical construction with the single tramway. The estimated cost for the paved single tramway is £6,000 per mile, and for the double tramway £12,500 per mile. Another form of rail (known as the "crescent rail") has been used for tramways to a limited extent, but it is considered much inferior to the rail before described, and is not likely to be much adopted. It consists of a curved plate of wrought-iron about $2\frac{1}{2}$ in. wide, and weighs 24 lbs. to the yard.—The grooves for the flanges of the wheels are partly formed by the granite pitching, which cannot but be considered a very imperfect contrivance. In the American system of tramways the longitudinal timbers are tied together by 4 in. planks instead of with iron bars, the planks being placed under the longitudinal timbers. In other respects the American tramways vary but little in construction from the tramway described. The rails first used were similar in form to Train's rail, and were now in a great measure superseded by the improved rail. The carriages proposed by the London tramways are to weigh 33 cwt. The length of the body of the carriage is to be 16 ft.; the width over all, 6 ft. 8 in. They are to carry fifty passengers, and are to be so constructed as to give 1 ft. greater space between the seats than is given by the omnibuses now in use. The maximum rate of fare is to be one penny per mile for distances above three miles, and 3d. is to be the least fare. The rate of traveling, including stoppages, is to be six miles per hour.

Tramways, said Mr. Measam, would doubtless give easier traveling and more commodious conveyances than are to be obtained at present, but here—excepting that the tramway companies are to maintain a portion of the public roadway over which they pass—the advantages of tramways seem to cease. It is surmised that a line of carriages passing to and fro every three or four minutes in one undeviating line, claiming priority of way, and scattering the general traffic, cannot but be productive of annoyances, to say nothing of the obstacles which the rails may cause. It is much to be doubted, Mr. Measam thought, whether all the disadvantages resulting from Train's tramway were alone due to the rail used by him—which, it must be remembered, had been in use for some time in the United States—or whether they were not, in a great measure, inseparable from the working of the tramways on a roadway of mixed traffic. Further objections to the introduction of tramways start up in the form of difficulties put in the way of connecting houses in their line of route with the gas and water mains and with the sewers. But the chief objection to street tramways as proposed to be introduced seems to be, that individuals acquire privileges and rights in the public highways not possessed by the community at large, and that the public property is appropriated for the use and trading purposes of private speculators. Although some strong measure was necessary to destroy the existing monopoly in metropolitan street passenger conveyance, to bring this about by so great an interference with the public rights as the permitting of individuals to construct permanent works on the public highways, is a remedy likely to produce worse evils than those it is intended to remove.

There is another consideration in favor of tramways, however, and that is the reduction of friction resulting from their use. On a good paved road the force of traction is about 24 lbs. for every ton weight of carriage, including, of course, the load. On a tramway it may be taken at 8 lbs. per ton, giving a mechanical advantage to the tramway on level surfaces of 3 to 1. On inclines the advantage rapidly decreases, and on a gradient of 1 in 26 (which it is believed, is the steepest incline there is on the proposed metropolitan tramways) the difference of the force of traction on a tramway as compared with a paved road is only as 117 to 100. Practically, it may be considered that a horse on a tramway will do the work of two horses on an ordinary road. The practical advantage of street tramways, therefore, seems to resolve itself into the fact that the same amount of traffic can be conducted at one half the expenditure of horse power necessary on an ordinary road. This advantage is purchased at the cost of the construction of the tramways, and the maintenance of a large portion of the highways. The estimated cost of the tramway from Whitechapel to Stratford is £45,000, excluding coach-houses, stabling, etc. The annual expense of maintaining the highway the company is bound to keep in repair, assuming the cost at one shilling per yard, would be about £1,600. On the other hand, assuming 120 horses to be the number required for conducting the traffic, there would be a set-off against the above specified expenditure of the value of this number of horses. Considering that commodious carriages are not necessarily restricted to the railway system, the omnibus proprietors need not much fear the rivalry of the tramway companies. That tramways are the best suited for omnibus traffic none but omnibus proprietors would deny, and if a portion of the public roads is to be set aside for omnibus traffic, no better mode of conducting it than by tramways could be devised; but considering the different kinds and the large amount of traffic that has to be accommodated, and the various uses to which the public roads are necessarily applied, Mr. Measam considered it would be more generally advantageous to restrict the construction of tramways, as has hitherto been the rule, to such roads as their promoters have an exclusive right to use.

In the discussion which followed the reading of the paper, the chairman said that with regard to the metropolis, tramways were unsuited to the wants of the traffic at large, although they might advantageously be adopted in such wide thoroughfares as were to be found on the Surrey side. In Cheapside trams would be out of the question. He was practically acquainted with the working of Train's tramway, however, and he was bound to say that there was not the slightest ground for saying that any accident was caused by the projection ($\frac{3}{4}$ of an inch) of his rails. There was no such thing as the breaking of good axles by going over the rails, but four or five people were specially paid to take broken-down carriages with bad axles and bad springs, and drive them over and over the rails until they inevitably had a "smash." There was no mechanical difficulty in the way of making tramways succeed, but the Legislature would (the chairman thought) be better advised if they gave powers to make increased thoroughfare accommodation rather than to construct tramways. Mr. G. W. Reid, from America, said that on that continent there were 10,000 or 15,000 miles of tramway at the present time. In Boston, a city built on exactly the same model as London, with narrow winding streets, tramways were laid in all the principal streets, and worked with perfect success in thoroughfares not wider than our own misnamed Broad-street City, and there was not one street in Boston in which the trams were laid down wider than Cheapside. Where the streets ran parallel and contiguous to each other, the "up" line was carried along one street, and the "down" line along another. Mr. Greaves, as engineer to one of the schemes just sanctioned by the select committee, adverted to the excessive cost entailed in getting private bills for public works through Parliament, and said that (seeing that tramways were undoubtedly public boons) he did not see why vestries and local boards should not lay down these trams. They had the power to pave the roads in what manner they pleased; then why not make a portion of the paving to consist of iron trams with grooves in them?

STEAM ENGINE PERFORMANCE.

Messrs. Farey and Donkin have recently made some remarkably thorough and comprehensive experiments in this direction, which are quoted and discussed in the London papers. The following are the particulars and the comments of "Engineering":

Experiments by Mr. Farey and Mr. B. Donkin, jun., upon a Double-Cylinder Jacketed Condensing-beam Steam Engine of 30-horse power nominal, constructed by Messrs. B. Donkin and Co., Bermondsey, London.

Dimensions of engine.	Diameter of cylinders 24 in. and $13\frac{3}{16}$ in., having strokes respectively 4 ft. 6 in. and 3 ft. $3\frac{3}{8}$ in.	Stroke of crank 4 ft. 6 in.

Indicated horse-power, taken with four indicators, diagram taken every half hour, work very constant.....	46.21 HP.
Pressure of steam in boiler house by mercurial gauge, taken every half hour, kept very constant, mean...	40.9 lbs.
Pressure of steam in engine house taken every half hour, mean......	$40\frac{1}{2}$ lbs.
Duration of experiment..............	10 hours.
Revolutions of engine per minute, by counter, mean speed.............	32.48 rev.
Vacuum in condenser by mercurial gauge, mean.....................	27 in.

Condensing water. The temperature and quantity were taken constantly by a self-acting recording photographic apparatus, as described in "Engineering," July 17, 1868.	Temperature.	Going in from a deep artesian well quite constant	53°
		Coming out, taken photographically mean.	89.54°
		Degrees of heat put into condensing water or rise.	36.54°
	Quantity.	Quantity of water per min., measured over a tumbling bay 6 in. wide, height recorded photographically,	408.32 lbs.
	Pound-degrees.	Lb.-degrees per min., or units of heat 408.32 lbs.×36.54°	14,920 lbs.
		Lb.-degrees per min. per indicated horse-power $\frac{14,920}{46.21}$......	322.87 lbs.

Water from Steam jackets.	Temperature.	Taken every quarter hour, hour, mean............	207°
	Quantity (from a steam trap).	Total pounds accurately weighed...............	$1,783\frac{1}{2}$ lbs.
		Pounds per minute......	2.97 lbs.
Feed water taken from Water Company.	Temperature.	Taken every ten minutes, mean.	$74\frac{1}{2}$°
	Quantity.	Total water evaporated in pounds	$10,404\frac{1}{2}$ lbs.
		Pounds per hour..........	1,040.4 lbs.
		Pounds per minute	17.34 lbs.

Description of boiler; vertical tubular.

Total quantity of coals burnt, accurately weighed (quality of coals—Welsh, but very inferior, great deal of dirt, shales, cinders, and clinkers	1,204 lbs.
Pounds water per pound coal burnt, or efficiency of boiler with this coal..	8.72 lbs.
Pounds coal per I.HP. per hour.......	2.61 lbs.
Pounds water evaporated from temperature of $74\frac{1}{2}$° per I.HP. per hour	22.51 lbs.
Expansion with steam cut-off at about $\frac{7}{16}$th stroke in small cylinder, allowing for passages and clearances, about..........................	11 to 1
Number of indicator diagrams taken, four always taken simultaneously, two at top and two at bottom of the two cylinders.	84
Temperature of outer air, fine day	67°
Temperature of steam-engine house, mean.	76°
Height of barometer	30 in.

Tallowed cylinders twice, $1\frac{1}{2}$ pints tallow used, also 1 pint of oil for all other parts.

This same steam engine indicated, when running empty, including cold water pump, was found to take $3\frac{1}{4}$ indicated horse-power.

Other experiments on this engine gave a result of about 300 pound-degrees at $\frac{1}{4}$th cut-off in the high pressure cylinder, instead of 323 pound-degrees at $\frac{7}{16}$ths.

In this experiment the vertical boiler evaporated only 8.72 lbs. water per pound of inferior Welsh coal, but in other experiments on the evaporative power of this boiler, when using a better quality of Welsh coal, and evaporating double the quantity of water in the same time, the result was 10.01 *lbs. water per pound coal*, with feed water at 61° temperature. Had this been the case in the above experiment, the quantity of coal consumed would have been $2\frac{1}{4}$ *lbs. of coal per indicated horse power per hour*.

The trial was conducted throughout with great care, four engineers being employed to take indicator diagrams simultaneously from the upper and lower ends of the two cylinders every half hour; while a fifth engineer checked the registration of the photographic apparatus by noting every quarter of the hour the rate of flow and temperature of the water from the hot well. A sixth engineer observed the boiler pressure, and kept account of the weight of coal used; while a seventh measured the quantity and temperature of the feed-water, and an eighth recorded the quantity and temperature of the water drawn from the steam jacket.

The results above recorded are of great interest, and by analyzing them we shall be enabled to show approximately the manner in which the heat generated by the combustion of the fuel is disposed of. In the first place we may assume that, as the coal was of inferior quality, it would not, on an average, be capable of yielding more than about 13,500 units or pound-degrees of heat per pound consumed; and as the rate of consumption was almost exactly 2 lbs. per min., we may fairly take 27,000 units of heat per minute as the gross quantity of heat theoretically available. The quantity of water evaporated per minute is given as 17.34 lbs., this water being converted into steam at a pressure of 40.9 lbs. above the atmosphere. The total heat of steam at this pressure is 1,201.6, or, say, $1,201\frac{1}{2}°$, and as the feed-water was supplied at a temperature of $74\frac{1}{2}°$, each pound of water in being converted into steam would absorb $1,201\frac{1}{2}-74\frac{1}{2}=1,127$ units of heat; and the total amount of heat thus absorbed per minute would be $1,127\times17.34=19,542.18$, or, say, 19,542 units. Again, if we assume 24 pounds of waste gases to be evolved from the furnace per pound of fuel burnt, and further assume that the specific heat of these gases is .24, and that they were discharged into the chimney at a temperature of 400° above that at which the air was supplied to the fire (all fair assumptions), we get $2\times24\times.24\times400=4,608$ units as the quantity of heat carried off per minute by the waste gases. We can thus approximately account for the heat generated per minute by the combustion of the coals, as follows:

	Thermal units.
Heat absorbed by the generation of steam,	19,542
Heat carried off by waste gases..........	4,608
Heat lost by radiation, imperfect combustion, etc..............................	2,850
Total	27,000

Of the 17.34 lbs. of steam produced per minute, 2.97 lbs. were condensed in the steam jacket and discharged as water at a temperature of 207°. Of the steam thus condensed in the jacket, each pound thus gave up $1,201.6°-207°=994.6$ units of heat, and multiplying this number by 2.97 we get 2,953.962, or, say, 2,954 as the number of units of heat per minute given up by the steam jacket. The weight of steam admitted into the cylinders of the engine (supposing no condensation to have taken place on the way from the boiler) would be $17.34-2.97=14.37$ lbs. per minute, and as the steam was ultimately discharged into the hot-well as water, at a temperature of 89.54°, each pound must have had abstracted from it on its way through the engine $1,201.6-89.54=1,112.06$, or, say, 1,112 units of heat. We thus have $14.37\times1,112=15,979.44$, or, say, 15,979 units as the quantity of heat given out per minute by the steam during its passage through the engine, and adding to this the 2,954 units given up by the steam jacket, we have a total quantity of 18,933 units per minute to be accounted for.

It will be noticed that the quantity of heat just mentioned is less by 609 units than that absorbed in the generation of steam, this deficit being caused by the water being drawn off from the steam jacket and discharged from the hot-well at higher temperatures than it is supplied to the boiler. Thus the 2.97 lbs. of water withdrawn from the steam jacket had a temperature of 207°, or $207-74\frac{1}{2}=132\frac{1}{2}°$ higher than that of the feed; and $2.97\times132.5=393.525$, or, say, $393\frac{1}{2}$ units are thus accounted for. Again, the condensed steam in the hot-well had a temperature of 89.54°, or 15.04° higher than that of the feed, and multiplying this by the weight of steam passing into the hot-well per minute, we get $15.04\times14.37=216.1248$, or, say, 216 units thus disposed of, a quantity which, added to the $393\frac{1}{2}$ units above accounted for, gives $216+393\frac{1}{2}=609\frac{1}{2}$ units, or half an unit more than the deficit above mentioned. The discrepancy of half unit is of course due to the decimal parts of an unit being neglected in our former calculations.

To return now to the 18,933 units of heat per minute, which have to be accounted for. In the first place, as the engine was developing 46.21 horse-power, $46.21\times33,000=1,524,930$ foot-pounds of work were being performed per minute, and dividing this number by 772 (Joule's equivalent), we get 1,975 as the number of pound-degrees or units of heat transformed into work. Next, it will be seen, on reference to the report of the experiments, that 408.32 lbs. of water were discharged from the hot-well per min., and subtracting from this quantity the 14.37 lbs., resulting from the condensation of the steam passed through the engine, we get 393.95 lbs. as the actual quantity of water which was raised in temperature 36.54°; and $393.95 \times 36.54 = 14,394.933$, or, say, 14,395 units of heat per minute are thus accounted for. We may thus say that the 18,933 units of heat per minute were disposed of as follows:

	Thermal units.
Converted into work	1,975
Imparted to condensing water	14,395
Lost by radiation, etc	2,563
Total	18,933

The summary is a very striking one. It shows that even in an engine of thoroughly good design and workmanship, working with what is considered a very low consumption of fuel, but about 10.4 per cent of the total amount of heat parted with by the steam is converted into useful work, whilst rather over 76 per cent is imparted to the condensing water, and about $13\frac{1}{2}$ per cent lost from radiation and other causes.

TEST OF AGRICULTURAL STEAM ENGINES.

A correspondent of "Engineering," under the head of "Steam Cultivation and R. A. S. E. Prizes," writes as follows:

That steam cultivation is approaching success, no one who has watched the various phases it has passed through can doubt, but up to the present moment it can scarcely be called triumphant, and the reason seems to me simple. Horse work upon a farm consists not merely of ploughing and cultivating, but also of a vast amount of cartage in drawing out manure, bringing home crops, taking produce to market, and bringing back lime and other artificial manures from the railway station. Now until a steam engine is able to do the heavy part of this work, in addition to ploughing, none but large and wealthy farmers or rich amateurs will be able to enjoy the luxury and the benefit of a steam plough. For a steam engine to be a thoroughly economical farm implement, it must, in fact, be able to exercise economically three distinct functions.

1. It must be suitable to drive thrashing and other farm machinery.

2. It must be able to plow and cultivate efficiently.

3. It must be a good and handy traction engine, able to draw heavy weights along the roads, and to haul out manure during dry and frosty weather, to suitable central positions on the farm.

But up to the present time we have no engine that will perform these three things economically. We have engines that will do two of them, but none that will do all three. Aveling and Porter make a very efficient although heavy traction engine, which will also drive farm machinery, but they are non-plussed when they come to ploughing. Fowler and Co., Garrett and Sons, and Howard & Co., make good enough ploughing engines, which will also drive ordinary farm machinery, but they are beaten when they attempt to work as economical traction engines.

The Royal Agricultural Society of England must move onwards, by offering a premium for an engine which shall subserve all three purposes. But unless the conditions on which the award is to be made be very carefully considered, the object will not be attained.

It must be evident to any one that the prime cost of the machinery is a very material element, but unless some data are given to fix the cost, an unscrupulous maker may call his engine such a power and at such a price, and when he comes to supply others, may give a totally different machine. Heretofore it has been the custom to talk of engines as being so many horse power, but when one comes to ask what this horse power is gauged by, we are generally told that the size of the cylinder is the criterion. Now there could not be a more fallacious guide. An 11-in. cylinder is usually called a 12-horse engine, and by the best makers that size of cylinder will be put on to a boiler having 240 square ft. of heating surface, and will be called a 12-horse engine, for the best makers allow about 20 square feet of heating surface for each nominal horse power. Again an 8-in. cylinder is usually called a 6-horse engine, being about half the area of the 11-in. cylinder, and if both cylinders work at the same speed, no doubt the large cylinder will do about twice as much work as the small one. But suppose we put an 8-in. cylinder on to a 12-horse boiler (240 square ft. of heating surface), and drive it *twice as fast, the small cylinder will then do rather more work than the large cylinder.* Would it not be folly, then, to call that engine a 6-horse engine, simply because we had changed the cylinder? But it may be said, why not drive the large cylinder fast also? The reply is very simple: the boiler would be unable to supply it with steam because a certain area of heating surface will only evaporate a certain quantity of water economically.

It is plain, then, that the heating surface in the boiler is the true test of the power of an engine, and if it be agreed by all that 20 square ft. of heating surface shall be denominated 1-horse power, then the engineer who can develop the greatest amount of *useful effect* out of that extent of heating surface, is the most successful engineer; and the man who can produce an engine at *the lowest prime cost in proportion to the work done* is the cheapest engineer. But here another element drops in. If an engineer is reckless of the quantity of coal that he uses, he can so dispose his heating surface as to make it evaporate much more than it would do if it were arranged to absorb the principal portion of the heat developed by the combustion of the coal. Therefore, the quantity of coal used in proportion to the work done should also enter into the calculation, for coal is an expensive article. The quantity of water, too, is a matter of great moment. 1 lb. of coal well managed will evaporate about 10 lbs. of water, and when an engine is working as a traction engine far from home, or as a ploughing engine on a steep and dry hill-side, it is quite possible that to supply it in such situations with water might actually be as expensive as to supply it with coal. If, then, one engine will work for a whole day with, say, 400 gallons of water, and another engine doing the same amount of work requires 1,000 gallons, surely that ought to be considered in awarding a prize.

Weight, too, is another element. A very heavy engine is difficult to move about over farm roads and along soft headlands; and if it breaks through the skin of a cross country road, it will often involve its owner in very unpleasant disputes.

The extreme width, too, of the engine ought to be limited. Few farm-gates are more than 8½ ft. in the clear. Now Messrs. Howard's engine, I believe, is 8 ft. 9 in. wide, and to pass such an implement through an ordinary farm-gate is impossible. Messrs. Aveling and Porter's engines are, I believe, 8 ft. 2 in. wide, and to guide those through an ordinary farm-gate is plainly a work of difficulty. Such wide machines, too, are very awkward on country roads, where they have to pass wagons, carts and carriages. The R. A. S. E. might easily name a maximum width, which no manufacturer intending to compete should exceed; 7 ft. seems to me ample to cover everything, and if a manufacturer cannot produce a good engine not exceeding that width, he had better give way and allow men of greater ingenuity to take his place.

It is pretty plain, too, that any engine to be useful for ploughing or traction purposes should be able to go up and down steep inclines without uncovering any portion of the heating surface that is exposed to severe heat, for it is extremely dangerous. An engine, when ploughing, may have, for many days to be working up or down an incline of 1 in 8, or even steeper. Now, if an engine be so constructed that with the ordinary supply of water its firebox would be uncovered upon such an incline, it is plainly unfit for its work.

It appears to me, then, that the Royal Agricultural Society might lay down as a *sine quâ non:*

1. That each engine intending to compete shall be capable of working as a ploughing engine, as a traction engine, and as an engine for driving ordinary farm machinery.

2. That no engine shall compete if, when working up or down an incline of 1 in 8, it uncovers any portion of its firebox to a less depth than 4 in. of water at the shallowest point.

3. That no engine shall compete if it is wider at any point than 7 ft., and to prevent this width being only temporarily diminished by decreasing the breadth of the wheels, no engine should compete if each driving wheel of the engine be less than 1½ in. broad for each ton weight of the engine, when loaded with 10 hours' coal and 2 hours' water. That is to say, a 10-ton engine must have 15-in. driving wheels at the least.

If these matters were once agreed upon, then it seems to me that the goodness of each engine in each particular department, if I may use the word, could be determined by allotting to it so many points, and whichever engine gained the most points would gain the first prize, just as in a competitive examination for the Indian Civil Service.

In making the actual trials, I think that two will be enough, for if an engine works cheaply and well as a ploughing engine, and also as a traction engine, we may safely assume it will be an economical engine for driving ordinary farm machinery. But in trying an engine with its cultivating machinery, it is a question whether it should be tried both with a plough and with a cultivator, or only with one of them. It seems to me that the plough is the implement most thoroughly understood by farmers, and is, therefore, the fairest implement by which to test the success of steam cultivation; for if it works the plough well, we may safely assume it will work the cultivator equally well.

In trying the engines as ploughing engines, each should have a plot of three acres given to it, the choice of plots being determined by lot. Then the engines and the ploughs being all in their places, the fires should be thoroughly drawn at a given signal, and the valve opened to bring down the steam to the pressure of the atmosphere. When this was done, and the judges had satisfied themselves that the fires were thoroughly drawn, and the steam pressure run down to that of the atmosphere (a watchman being placed at each engine) accurate account should be taken of the height of water in each boiler, and the quantity of water in each tender, a certain weight of coal, and a small quantity of wood and shavings should be given to each engine, and at a given signal the fires should be lighted, and the trials should commence, time being duly marked. As each engine finished its task, time could be again taken, and the results deduced as follows:

1. Divide the weight of soil moved in an hour by the square ft. of heating surface in the boiler.

2. Divide the weight of soil moved in an hour by the gallons of water used.

3. Divide the weight of soil moved in an hour by the number of men employed; two boys, provided they are really doing boys' work, to count as one man.

4. Divide the weight of soil moved in an hour by the lbs. of coal used.

5. Divide the weight of soil moved in an hour by the cost of the apparatus

Each of these things to count one point to the winner, and whichever engine gains most to have the first prize, and the next the second prize. But if any engine gains four out of the five points, that engine to get a gold medal and the first prize, and the next engine to get only a third prize. Or if any engine gains all five points, such engine to get a gold medal and sole prize, no other prize being awarded.

In trying the engines as traction engines, I should be inclined to make them start cold and draw a load over a given piece of ground, up a steep incline, say, 1 in 12. Whichever engine first brought its steam up to a given pressure should gain *one point*, and after each engine had drawn its load (of such weight as its owner might fix upon) along the given distance I would decide the trial as follows:

1. Divide the net load by the time, the winner to gain *one point*.

2. Divide the net load by the square ft. of heating surface, the winner to gain *one point*.

3. Divide the net load by the lbs. of coal used, the winner to gain *two points*.

4. Divide the net load by the gallons of water consumed, the winner to gain *two points*.

5. Divide the net load by the weight of the engine, the winner to gain *two points*.

6. Divide the net load by the cost of the apparatus, engine, and tracks, the winner to gain *two points*.

This makes eleven points in all, and if any engine should gain the whole it should receive a gold medal and sole prize, or if any engine should gain ten out of the eleven, that engine to have a gold medal and the first prize, and the next engine a third prize only. But if no engine gained so many as ten points, then the engine which gains most to have the first prize, and the next highest to have a second prize.

To prevent disputes as to what should be considered the net load, it should be arranged that the total load drawn by the engine, *exclusive of its own weight*, should be considered the net load, for if you attempt to deduct also the weight of the truck which carries the load, trucks would be used in trial far too light for practical farm work, and our object is to get not a racing engine, but one suitable for ordinary farm work.

As to pressure, it has been the custom heretofore to limit this to 50 lbs. above the atmosphere, which seems to me an unreasonable limit. When we have locomotives working at 150 lbs. and 180 lbs., why should a farm engine be limited to 50 lbs? As far as danger is concerned, 50 lbs. is quite as dangerous as 180 lbs., for every good engineer makes his boiler in proportion to the strain. At all events, a pressure of nine atmospheres, or, say, 120 lbs. on the square in. above the atmosphere, might be recognized; but each competitor might be called upon to declare the dimensions and substance of the various parts of his boiler, and the species of iron used, and if by calculation the breaking strain is found to be less than six times the maximum declared working pressure, then let the engine be disqualified.

If engineering and agricultural newspapers, too, would take up this matter and ventilate it, we might hope to see some proposal made for the trials in 1870, which would stimulate fresh engineering talent to enter the agricultural arena. A good manufacturer of railway locomotives would be a formidable competitor to all existing agricultural engineers.

THE BLAST FURNACES AT MIDDLESBOROUGH.

From the "Mining Journal."

There are now fifty-two blast-furnaces in operation in the immediate neighborhood of Middlesborough, besides ten more in course of building; there are about nine more of small dimensions, 45 ft. high, which are dormant, and are not intended to be again used. Besides these there are in the Tyne, Durham, and Whitby districts, thirty-eight furnaces in blast, two building, and sixteen not in use, giving a total of one hundred and eighteen blast-furnaces in the north-eastern district, either at work, or will shortly be available for the production of pig-iron. Of the fifty-two furnaces in the neighborhood of Middlesborough, their height varies from 60 to 85 ft., and their diameter is proportionately large. As an instance of economical management in the production of pig-iron, the blast-furnaces at Eston Junction, worked by Bolckow, Vaughan, and Co., may be cited as having adopted the latest mechanical appliances calculated to economize labor and reduce the cost of production. There are five furnaces at Eston Junction, 85 ft. high; the make of each averages about 350 tons of iron per week; one occasionally makes upwards of 400 tons per week. Hot-blast is used in every furnace in the district. There are five kilns for calcining the ore. One kiln will supply ore sufficient for one furnace. Each kiln is 21 ft. in diameter, 45 ft. high, having a circular frame-work of ½-in. iron plates, and 18-in. lining of fire-brick inside; these are of sufficient strength to carry a locomotive road on the top of them. One ton of coal is required to calcine 40 tons of ironstone. The calcined ironstone falls direct into the barrows from the bottom of the kilns, on raising the sluices placed for stopping the outlets, so that the labor of filling with shovels is saved. Behind the kilns are erected the gantry, about 45 ft. high, where the hoppers for storing coke are made. There are two hoppers, holding 600 tons each. The coke is let out as required by sluices, made at different parts on the underside of the hoppers, and runs direct into the barrows. A good deal of coke is thrown loose besides into stock, but it is no doubt more economical to stock it in hoppers only. The limestone is obtained at Forcett, and is tipped from the same gantry into stock, from whence it is taken to be broken by hand labor; this could be done to advantage by machinery. The calcined ore, coke, and limestone are now to be raised to the top of the furnaces; this is effected by water-balance machinery. There are two lifts for the five furnaces. Water is forced up to a tank at the top of each lift. There are two carriages for each lift ascending and descending, the cistern in the descending carriage being filled with water to raise the ore, coke, etc., in the ascending one. This is the usual method of lifting materials in this district, but Sir W. Armstrong's hydraulic machinery is in operation at the Clarence Works. Compressed air is used at Linthorpe and Tees Side furnaces, and a steam-engine and inclined plane are used at Acklam furnaces.

The blast-engines in the Middlesborough district are of various forms; there are several of the beam, connecting-rod, and fly-wheel type; a few of Slade's patent slide cylinders. Those lately erected are principally of uniform size and construction; they are on the inverted-cylinder principle, are supported on cast-iron framework, and occupy a small space. Steam-cylinder at top 30 in., blowing-cylinder below 66 in. diameter, 4-ft. stroke; beneath this the piston-rod and connecting-rod extend to the fly-wheel shaft, on which two fly-wheels, and an eccentric work, the shaft being being on a level with the floor. These engines go from 40 to 50 strokes per minute, and one of them is capable of supplying a large furnace with blast at a moderate speed. There are small engines, usually placed in the same house with three or four blowing-engines, for forcing water to the tanks on the engine-house and at the top of furnace lift. It should be observed that where locomotive power is not used to bring materials to the top of the calcining kilns, and coke and limestone to the gantry, this is effected sometimes by a vertical lift, where steam or compressed air is the motive power; the wagons, after being tipped or discharged, are dropped down at the opposite end of the gantry and the row of calcining kilns; as these are placed usually all in one line, with a double road on the top for the transit of the trucks from one end to the other; this is a very compact arrangement on a level surface. In a few cases these materials are raised by an inclined plane and steam-engine to the top of the gantry.

The steam-boilers used in the district are nearly all of the same type. Some of these have been 20 years in existence, at work night and day. The boilers are plain cylindrical, 70 ft. by 4½ or 5 ft., slung from five cast-iron arched girders, by three straps from each girder, attached to an angle-iron piece riveted to the boiler. The blast-furnace gas is now always used to heat these boilers, the flue being a single straight one under each boiler to the chimney-flue. In some cases the gas is sufficient to heat both the boilers and hot-blast pipes. In many of the works, however, coal is used in addition. Why this is so I am unable to explain. The blast-furnaces being closed at the mouth, the gases are brought down into large wrought-iron cylindrical tubes, lined with fire-brick. In two cases the gases are brought down to an arched culvert, made underground, and from that distributed to the various blast-stoves and boilers. The pressure of blast maintained is 3½ to 4 lbs. The temperature of blast is from 1,000° to 1,100°. A great part of the economy of these blast-furnaces is due to the high temperature of the blast, and their great height. The difference in consumption of coke is so marked as to have caused the abandonment of furnaces 50 ft. high, and erecting others in their place, 70 feet high and upwards. The large production is obtained from their great diameter. An improved boiler is used at Newport Works: it has one tube; the gas passes through this, and returns under the boiler, giving much more heating surface than that before described. The whole of the boilers in the district are covered either with bricks and mortar—an air-space intervening between that and the boiler—or they are covered in a few cases with a patent composition. Each boiler is fitted with two safety-valves, two floats, two sludgers, one float, with whistle, dial, and pointer.

The blast is heated generally in the common Λ-shaped pipes, but at Ormesby Works the blast is heated by Siemens' stoves; these are giving satisfactory results. The air after passing for two hours through one heated chamber is diminished in temperature at its exit only 100°, and is then transferred to another chamber. The Cargo Fleet blast-furnaces are run off every eight hours. A large furnace at Norton runs off the metal both in front and back at each cast every 12 hours. These are some of the principal features of the blast-furnace economy of this district; it is evident that large outlay is required for these immense structures, the engines, and mechanical appliances, but the result is to make the manufacture a more profitable one with the present process.

COMPOSITION OF SEWAGE.

THE LONDON SEWAGE—WHAT IT IS AND WHITHER IT GOES.

From "the Engineer."

By "sewage" is commonly understood anything that flows through a sewer. But the contents of a sewer are generally very composite in their character. Sewage absolute is comparatively extremely small. Apart from water supply, rainfall, and subsoil water, an average individual contributes to the sewers at the rate of only a little more than a quart per day, solid and fluid together. Dr. Parkes, in his standard work on "Practical Hygiene," gives the daily fœcal matter at two ounces and a half, and the urinary matter at forty ounces. In bulk this would be about 73 cubic inches. In round numbers this would amount in the course of a year to one hundred gallons, or a thousand pounds, or very nearly sixteen cubic feet. Reckoning the population of London at 3,000,000, the yearly amount of absolute sewage would be 48,000,000 cubic feet, equal to 300,000,000 gallons, or 1,339,300 tons. To this we will add in the first place, the rainfall, as distributed over the area of the metropolitan district. In his evidence before the Select Committee on the Sewage of the Metropolis in 1864, Mr. Bazalgette gave the area of the district as 116 square miles, with an average annual rainfall of twenty-four inches. But of this quantity the same authority reckoned that a proportion ranging from one-half to two-thirds would never enter the sewers, being lost by evaporation and absorption. Accordingly the rainfall which mingles with the sewage may be estimated at ten inches per annum over the 116 square miles, or, in round numbers, 72,-000,000 tons, equal to 2,580,000,000 cubic feet, or 16,125,000,000 gallons. With a population of 3,000,000, this will give for each individual an annual average of 860 cubic feet, equal to 5,375 gallons, or twenty-four tons. In the next place we come to the water supply. In 1867 the water companies supplied London with an average of 98,600,-248 gallons per day, of which about 81,033,-800 gallons were used for domestic purposes. A daily allowance of thirty gallons per head would be just 90,000,000 gallons for a population of 3,000,000. We may fairly take this as the quantity going into the sewers, equal, therefore, to 5,268,000,000 cubic feet, or 147,000,000 tons, being at the rate per head of 1,752 cubic feet per annum, equal to 10,950 gallons, or 49 tons, leaving the brute creation—horses, cows, donkeys, dogs, etc.—out of the reckoning. We thus form an idea as to the contents of the London sewers. The effect of the rainfall is probably under estimated. Much of the absorbed rainfall may be considerered to find its way ultimately into the sewers by percolation through the brick-work. It is also probable that the area which contributes rainfall to the London sewers is larger than the space referred to in Mr. Bazalgette's evidence.

Returning now to our figures, we observe that while each individual contributes to the contents of the London sewers at the rate of nearly 1,000 lbs. per annum (less than half a ton), this is supplemented by 24 tons of rainfall and 49 tons of water supply. Reckoned daily, these quantities become $42\frac{1}{2}$ oz. of absolute sewage, 147 lbs. of rainfall, and 300 lbs. of water supply. The total yearly average per head is 73.4 tons, equal to 2,628 cubic feet, or 16,425 gallons, the daily average per head being 7.2 cubic feet, equal to 45 gallons or 450 lbs. Reckoning that an acre of water an inch deep will weigh 100 tons, the unmixed sewage of London for one year will cover a space of 10,000 acres to the depth of an inch and a-third. But the proportion of rainfall which we reckon as entering the sewers would cover an equal area to the depth of 6 ft., while the water supply would cover such an area to the depth of more than 12 ft. A man walking through the sewage would scarcely do more than wet the soles of his boots; whereas the estimated portion of the rainfall would cover his head, and the water supply would leave him 6 ft. under. If to the proportion of the rainfall we add the water supply, we find that, whereas the unmixed sewage of the year covers 10,000 acres to a depth of only an inch and a-third, the sewer rainfall and the water supply combined will cover the same space to a depth of 18 ft. Thus, in the case of London, that which is commonly called sewage has only one part in 164 composed of pure human sewage, the remainder being rainfall and water supply. So far as the yearly average exceeds seventy-three tons per head of the population, the absolute sewage may be considered as undergoing a dilution even greater than the foregoing. The discharge from the metropolitan outfall at Crossness is often considerably in excess of this quantity. In the week ending May 29th, the daily discharge at Crossness was 238,840 cubic meters, or about 238,000 tons. Taking the population of the southern area at 1,100,000, this would show more than 48 gallons per head, or at the rate of nearly 80 tons per head per annum. In that week the rainfall was 1.12 in.

So great a degree of dilution might make it appear that London sewage was a very innocent thing. But it must be remembered that absolute sewage is an extremely powerful agent. The fœcal matter of the metropolis from human sources alone is equal to more than 209 tons per day, or 76,000 tons per year; in addition to which the urinary matter amounts to 3,348 tons per day, or 1,-222,000 tons per year. With all this there goes down a large amount of rubbish and detritus from the roads, as well as refuse fluid and material from manufactories. According to the present system of metropolitan drainage, the sewers discharge themselves into the river, the Metropolitan Board of Works providing that there shall only be two outfalls—one near Barking Creek, and the other at Crossness. As yet the former is not in complete operation, owing to the unfinished state of the northern low level sewer. On the south side the works came into full operation some time ago. We have, therefore, to consider the probable effect of casting the enormous mass of the London sewage into the Thames at the points indicated. From the Barking to the Crossness outfall is nearly two miles in a direct line. The Thames Conservancy Board, as far back as June, 1867, complained that extensive sewage shoals were being formed in the bed of the river. The report of their engineer, Mr. S. W. Leach, showed that near the northern outfall a space of more than 40 acres, and near the southern outfall of about 120 acres of the bed of the Thames was covered by a deposit of sewage mud, having a depth in some places of fully 7 ft. "The character of the mud," says Mr. Leach, "shows clearly enough whence it has come." Dr. Letheby examined some samples of the deposit, and fully confirmed the opinion expressed by Mr. Leach. "The mud in each case," said Dr. Letheby, "was black and fœtid, and in a state of active putrefactive decomposition." When examined with a microscope, it was found to consist of "broken-up sewage matter, with the remains of myriads of animalculæ, and a large quantity of carbonate of lime in a partly crystalline state." The presence of this last-named ingredient in an unusually large proportion was cited by Dr. Letheby as evidence that the alkaline constituents of the sewage were "decomposing and precipitating the calcareous constituents of the water, and thus adding to the filth of the deposit." On the attention of the Metropolitan Board being called to these allegations, Mr. Bazalgette replied that the mud deposits in the Thames, over a range of about two and three-quarter miles in the vicinity of the outfalls, had in certain places undergone an increase of 983,000 cubic yards between the years 1864 and 1867; but in certain other places along this range of the river there had been a decrease in the mud deposits to the extent of about 923,000 cubic yards, leaving the net increase, therefore, only 60,000 cubic yards. Mr. Bazalgette considered this "a very small increase in the total quantity of deposit." But it is equal to 1,620,000 cubic feet, or something more than the entire quantity of fœcal matter cast out in the space of seven months. At that date the outfalls had only been in operation for three or four years, and for a considerable portion of that time very partially. What is the present state of affairs may be soon known from the report of Mr. Rawlinson, who has been instructed by the Home Secretary to inquire into the condition of the river near Barking, the inhabitants of that locality having long ago memorialized the Government on the subject. The article quoted then goes on to show that there are evidences of the salt and sewage of the Thames permeating the bed of the river and contaminating the wells of water works on its banks, as at Crossness. As this is of merely local interest we do not quote it.

STEEL RAILS.—The gradual increase in the price of iron is indicated, not merely by the current quotations, but by the multiplication of blast-furnaces. In the Cleveland district an unusually large number of new furnaces is being erected; and although the production will be thus increased, it will probably be some time before prices will again fall. The gradual tendency to an increase of wages, caused, in part by an unusually strong disposition on the part of large bodies of workmen to emigrate, must tell also in the price of rails. In the mean time, notwithstanding the approaching lapse of Mr. Bessemer's patents, the steel rail trade continues good, and numbers of companies who have decided to employ steel in place of iron, and who must have rails, of some kind, immediately, are ordering freely in steel, the Great Northern Company being now in the market for a thousand tons. The untrue assertion, so industriously repeated in certain interested quarters, that the royalty will be diminished by £2 per ton after February next, is now understood in its true character; and railway companies perceive that even were there no general rise in prices, the diminished royalty will not be more than 18s. or 19s. a ton on that now in force, and of this the companies cannot expect to secure even a half.—*Engineering.*

UTILIZATION OF BLAST-FURNACE SLAG FOR MORTAR.

Compiled and Translated from an article in "Zeitschrift des Vereins Deutscher Ingenieure."

When, in the preparation of mortar, granulated or ground blast-furnace slag is used in the place of sand, a much smaller quantity of lime is necessary to make a well binding mortar, an advantage which is of great importance for many districts. Most blast-furnace slags, containing alumina, lime and silica in certain proportions, are dissolved by acids, the silica only being precipitated in a gelatinous state. The same takes place when natural cement is treated with acids. Blast-furnace slag, like tarrace and cement, contains silica in a condition in which it is liable to enter new chemical combinations. Silica, in the shape of sand or of quartz, forms, likewise, a chemical combination with the lime in mortar; but only when they have been in contact for a long time. The principal reason why this sand-mortar gets hard, is that the lime combines with carbonic acid taken from the air. As this combination takes place but slowly from the outside, mortar gets hard at first on the surface, the interior remaining soft for some time. If blast-furnace slag of a certain composition is used, the mortar gets hard more rapidly and through its whole mass, because the lime combines with the silica, in the same way as this is the case with tarrace (a kind of puzzolana) or with cement.

Thus mortar, made from blast-furnace slag and lime, hardens:

1. By the formation of carbonate of lime, as ordinary mortar does, and besides,

2. By the formation of chemical compounds of silica and lime.

These reactions are aided and quickened by a repeated contact with water and air. As mortar made from slags hardens quicker and more thoroughly, it does not require near so much lime and produces a more solid mass when hardened. When blast-furnace slag is ground fine it acts considerably better yet in the mortar, and can then be used even as a substitute for tarrace. It is then, also, a good material for plastering.

We communicate in the following the results of experiments, made by a committee of experts, at the Friedrich Wilhelm Iron Works (Prussia), under the direction of Mr. Langen, for the purpose of discovering the qualities and relative value of different materials used in the preparation of mortar and cement:

On the 17th of October, 1861, a number of samples of mortar were prepared from different mixtures, to be tested afterwards when hardened. The materials used were,

1. Fresh calcined lime from Ruppichteroth.
2. Rhenish tarrace, just received.
3. Ordinary sharp sand, as used for masonry.
4. Granulated slag, in pea-size.
5. Fine ground slag.
6. Portland cement of Bonn.

Different mixtures of mortars were prepared from these materials, and small square blocks, 5 in. wide and 2½ in. high, were formed of them in wooden moulds. One-half of these test-blocks were exposed to the air, the other half were laid in wet ground for several months.

On the 12th of March, 1862, the samples were inspected, and were tested as to their solidity and resistance to pressure. The pressure was applied through a lever arrangement. The weight was increased very slowly, and the pieces had to withstand for some time the pressure of a certain weight, before the latter was further increased. The results were the following:

A.—RESULTS OBTAINED WITH SEVEN SAMPLES, HARDENED IN THE AIR.

Number of Sample.	Mixture.	Results of Exterior Inspection — Appearance and Hardness.	Result of crushing test. Sample was crushed by a load of
			lbs.
1.	1 lime. 2 sand.	The sample looked and had hardened like ordinary mortar..........	1,980
11.	1 lime. 1½ tarrace. 1½ sand.	Considerably harder than No. 1...	7,380
3.	1 lime. 3 gro'd slag.	Considerably harder than No. 11. Structure fine and dense.	17,820
7.	1 lime. 5 gro'd slag.	Harder than No. 3. Equally fine and dense structure...	32,400
10.	1 lime. 2 gro'd slag. 1½ granl. slag.	Harder than No. 7. Structure less fine; the big grs. of slag distinctly visible.	21,420
13.	1 lime. 1½ gro'd slag. 1½ granl. slag.	Slightly harder than No. 10. Structure similar to No. 10........	15,080
5.	Pure Portland cement without any sand or lime.	Very hard.......	41,400

B.—RESULTS OBTAINED WITH FIVE SAMPLES, HARDENED IN WET GROUND.

Number of Sample.	Mixture.	Appearance and Hardness.	The sample was crushed by a load of
			lbs.
12.	1 lime. 1 tarrace. 1½ sand.	Not very hard...	5,600
4.	1 lime. 3 gro'd slag.	Considerably harder than No. 12. Structure fine and dense...........	11,700
14.	1 lime. 1½ gro'd slag. 1½ granl. slag.	Harder than No. 4. Structure less fine............	11,580
8.	1 lime. 5 granl. slag.	Harder than No. 14. Structure fine and dense........	25,200
6.	Pure Portland cement witho't sand or lime.	Very hard.......	42,800

The above results show that granulated or ground blast-furnace slag is a very valuable material for ordinary and for cement masonry, and that in the property of forming a very solid mortar, it stands in the middle between tarrace and Portland cement, being considerably superior to the former. The tests of the samples No. 7 and 8 prove that a great saving of lime can be effected by the use of slag. Ground slag has, therefore, a much higher value than the best sand. It looks and acts like cement, and shows the same kind of greasiness when mixed with fresh slacked lime. It would be a very valuable ingredient to mix with Porltand cement, to make the latter cheaper, and thus bring it into more extensive use. S.

PAPER BELTING.—Messrs. Crane & Co. of Dalton, Mass., have succeeded in making belting from paper, and the article is now used in all their own mills and several other manufacturing establishments. The belting is said to resemble the genuine oak-tanned leather, and to serve well both in a dry or damp atmosphere.

HEATING-FURNACE BOILERS.

From "The Engineer."

It is more than probable that as much steam is raised in Great Britain alone during each year, in small boilers, as would cost £150,000, if coal were specially burned to generate it. Furnace boilers may be counted by hundreds, if not by thousands; nearly all the iron we make in this country is smelted, and hammered, and rolled principally by the aid of steam raised from the waste heat or waste gases of our puddling, heating, and blast-furnaces. It might be supposed that everything would be known as to the generate powers of boilers so extensively used; while all that concerns their construction would have been settled on the best principles long since. Yet, strange to say, this is very far indeed from being the case. We have recently had occasion to investigate the subject pretty closely, and we find that the utmost ignorance, and probably, as a consequence, the greatest possible diversity of opinion, exists on almost every point connected with furnace boilers. No one, for example, appears to know how much steam five, ten, or a hundred square feet of heating surface in a furnace boiler should generate in an hour. An engineer putting down new works must, as far any written law goes, be absolutely in the dark. He can of course servilely copy what has been done by other engineers; but it by no means follows that he will of necessity obtain the same results. Boilers put down in apparently nearly the same way in different districts, manifest different powers of evaporation. This is bad enough, but when we turn to questions connected with the safety and durability of boilers, we find them still worse. Boilers are—we believe through ignorance—so badly designed, badly made, and badly set that explosions are of every day occurrence. Shall we say too much if we assert that the boiler engineering of our great iron districts is a disgrace to our profession?

The causes leading up to this result may, we think, be easily indicated. If once fairly examined we also believe that it is quite possible, that means may be found to raise furnace boiler engineering out of the slough of despond into which it seems to have fallen. One reason, then, why the most is not made of the furnace boiler is that it is always regarded as a matter of the most secondary consideration. The first point is that the draught of the furnace must not be interfered with. The boiler must be fitted to the draught, not the draught to the boiler. This is all right enough in one sense, and we willingly admit that when a boiler is used the heat in the stack cannot and should not be as great as though the products of combustion were thrown directly into it. But on the other hand, no one expects the products of combustion to escape from the flues of a furnace boiler at 300 or 400 degrees of temperature. The heat in the first instance is infinitely greater than it is in the flue of a Cornish boiler, let us say, and therefore even after a large proportion has been absorbed much must still remain for the stack. Is it not possible that by lengthening stacks a little it would be practicable to make furnace boilers somewhat more economical than they are?

Another reason why furnace boilers are not what they should be, lies in the fact before referred to, that no one knows how much steam any given boiler can make. No one can tell whether a furnace boiler of given construction is better or worse than another furnace boiler of totally different construction; so long as the iron gets hot soon, every one is satisfied except the manufacturer, who has to pay some thousands of pounds a year for additional steam raised in hand-fired boilers, and this while flame enough to raise twice as much steam as he gets out of these last-named boilers, is pouring from the throats of his re-heating and puddling furnaces. No one knows how much steam can be got out of a furnace boiler, because no one seems to have tried to know. In most ironworks all the boilers are coupled together, and the demand for steam in different parts of the mill is so very variable that it is next to impossible to say how much is being used, or how much is being made by any particular boiler. The only way to settle the point is to select two or three of the best types of furnace boiler, attach a good water meter to one of each type, and conduct a series of observations lasting over a month to determine how much water is really evaporated per foot of heating surface.*

We are convinced that a great field for improvement lies in the designing and construction of boilers to work with heating furnaces, and of heating furnaces to work with boilers. The sooner the matter is taken up, ventilated, and discussed, the better. At this moment keen competition has reduced the profits of the ironmaster so low that he has no money to waste in rising steam. Can none of our correspondents in the mining and ironmaking districts aid us to throw some light on the subject? Every scrap of authentic information is of value as tending to form a nucleus round which other facts may gather. Few subjects deserve more attention than furnace boilers at this moment, and we shall be pleased to hear what our practical readers have to say for and against particular types of boiler. A free discussion of the subject will be certain to do good; and such a discussion we hope to see started in our correspondence columns.

* This is a recommendation of the highest importance, and we hope it will be followed up in this country. We have recently got at some approximate results as to the evaporation in a boiler 30 ft. long, and 50 in. diameter, with two 17-inch flues, when used over a furnace *heating steel* rail ingots. The evaporation was only about one quarter as much as in the same style of boiler set in a battery, Cornish fashion and fired in the ordinary manner.—Ed. V. N. M.

ARCHITECTURE CONNECTED WITH STRUCTURES OF CIVIL ENGINEERING.

From a Paper read before the Society for the Encouragement of the Fine Arts, June 10, by Thomas Page, C. E., Acting Engineer of the Thames Tunnel, and Engineer of the New Westminster and Chelsea Bridges.

Considering that so many hundreds of millions of money have been expended in these kingdoms in works of civil engineering, and that in too many cases these works have not been distinguished by that architectural knowledge which has never been neglected in past ages, and very rarely indeed on the Continent, it is not surprising that the Council of a Society for the Encouragement of the Fine Arts, having before them the great examples of bygone days, when works of utility were coupled with artistic treatment, should draw attention to this subject at the present time, with the object of promoting a union of engineering science with the most severe of fine arts—viz: architecture.

During many ages the various kinds of works now appertaining to the civil engineer were executed by architects, and, as you are aware, the first architects were the kings and priests of the early ages. The constructors of the moles of Tyre and Sidon, the harbor of Alexandria, the port of Ostia, and all such undertakings, which were especially works of *utility*, were in reality done by engineers who were nominally architects. When, in process of time, these works of ultility increased in number and variety, in consequence of the extension of commerce and manufactures, they were entrusted to a class of men named *civil* engineers, to distinguish them from the *military* engineers, whose duties were those of attack and defense, while the former were engaged in the construction of roads, bridges, harbors, lighthouses, docks, and other hydraulic works, with their engines and machinery; and, lastly, on railways, of which about 14,300 miles have been executed in the United Kingdom.

The profession of the civil engineer is one of great importance in all progressive nations, and its members should be worthy of a calling which has numbered among its members the kings and priests of early ages, the Pontifex Maximus of the Romans, and the Christian Popes, the Cæsars, the Roman generals, and those succeeding them, down to the Great Napoleon, the offspring of the French Revolution, and the present talented Emperor, who, trained some time in England in the school of adversity, now occupies the throne of the French Empire, and exercises a controlling power in the European States.

In this country, the origin of the profession of civil engineers has been well defined in the preface to the reports of the eminent engineer, John Smeaton (the engineer of the Eddystone Lighthouse). These reports were published in 1812, and and although of great interest to persons who regard the profession of the civil engineer as an object of study, need not be further alluded to than in the following sentence.

The memoir states: "Civil engineers are a self-created lot of men, whose profession owes its origin, not to power or influence, but to the best of all protection, the encouragement of a great and powerful nation; a nation become so from the industry and steadiness of its manufacturing workmen and their superior knowledge in practical chemistry, mechanics, natural philosophy, and other useful accomplishments." From this rapid but preliminary sketch, I now come to the artistic division of the subject—"Architecture connected with structures of civil engineering," and I would draw your attention to the fact that the greater the dimensions of the structure, provided the outlines are graceful, the less the effect which can be produced by architectural decoration, because the mind, impressed by the vastness and beauty of the outlines, by the leading features of the structure, regards in a less degree those architectural features which in structures of minor importance are so pleasing. As an illustration of this idea, I will refer to two buildings which you may all know—viz: the beautiful Water Gate of Inigo Jones, now at the river end of Buckingham-street, Adelphi, and the noble structure of London Bridge, the work of the great engineering family of the Rennies. Every detail in the Water Gate is well worthy of study, and produces a most pleasing effect; but in the great structure of London Bridge, although the dentiled cornice and the simple parapet are so well adjusted as to form a most successful example of architectural application well worthy to be imitated, yet the size and proportion of the arches and piers are such that the architectural details are almost lost in the vastness and majority of the whole.

Referring back to the early works of utility, I would state that among the works of the Romans of an engineering character may be especially named those great aqueducts which supplied such volumes of water into Rome and other cities of the extended empire. These structures of essential utility were rarely devoid of architectural treatment. In some, the masonry was rusticated, the arch stones being plain, in others pilasters spring from the first tier of arches, as in the aqueduct of Merida in Spain. The division of the height of the aqueduct into arches upon arches, not only secured stability in structures so narrow, but formed a pleasing architectural effect, and a series of arches of a lesser span surmounting the whole, on which was carried the channel for the water, formed as it were an ornamental attic story, examples of which were given in the Aqueduct du Gard, that of Theodoric at Spoleto, and others. The practice of introducing small arches in the highest story of the aqueducts is followed by the architects of France as may be seen in the noble structures of Roquefavour, of recent construction, and that of Montpellier, of the last century.

There are two structures of early times to which I would especially refer on account of their lofty proportions. These are, the bridge at Alcantara, constructed in the reign of Trajan, and the Aqueduct of Spoleto, attributed to Theodoric, the truly great Gothic King of Italy, who died A. D. 526. The bridge, or "Alcantara," was constructed over the Tagus, in a depth of 40 feet of water, A. D. 105; and its height above the level of the river is 245 feet, making a total height of 285 feet, which is 80 feet higher than the towers of Westminster Abbey. It is to be deeply regretted that one of the arches of this noble structure was blown up by the British army in June 1810, when Marshal Victor menaced to cross the bridge. As to the Aqueduct of Spoleto, there are various accounts of its height. Some statements, among which is that of Gauthey, assign to it an elevation of 130 meters, while others state that it does not exceed 82 meters. The immense aqueduct which supplied Carthage, and of which Dr. Davis, the explorer of Carthage, and author of the work "Carthage and Her Ruins," has given a photograph in the frontispiece of his work, is 60 miles in length.

The character of the architectural treatment of an engineering work must of course depend upon the outline and style of the design. In a suspension bridge, the architecture of the piers is difficult, because so few forms will harmonize with the curve of the chains. In the design of the Chelsea Bridge, the piers consist of iron frames protected by an ornamental casing; each is surmounted by a large globe as a lantern. If any professional architect will examine the mouldings of the Chelsea Bridge, he will be pleased, I think, with their form and certainly will admire their execution.

But it is not, in suspension bridges, however noble and beautiful, as in the Menai Bridge, constructed by the great engineer Telford, so well known for his practical knowlege and his taste, that we must seek for the artistic feelings which this society desires to encourage. It is in the application of the arch, which in general can be applied under all circumstances, and which so well admits of architectural treatment. I have spoken of London Bridge, Waterloo Bridge, and Southwark, and I would now refer you to two designs of my own—one for Blackfriars, which was selected by the Committee of the Bridge House Lands for adoption, and the other is the approved design for Westminster Bridge. As the two designs are widely different, the treatment of them will explain my ideas of "Architecture connected with structures of civil engineering."

The great spans of the segmental arches of Blackfriars, the center arch of which is 280 feet, require piers of proportionate thickness; these are terminated above the cutwaters by massive pedestals of polished granite, intended to have been obtained from the quarries in the Ross of Mull, on part of the estate of the Duke of Argyll. These pedestals are surmounted by groups of sculpture selected from events in British history, which, in their elevated position, would have been seen with a sky outline, a condition so important for the best effect.

The imposing sweep of the arches renders ornament almost uncalled for, and so the spandrels only have an ornamented character, in which is introduced the River God and the armorial bearings of the City of London; the cornice is simple, and the parapet plain. In Westminster Bridge, on the contrary, the arches are of moderate span, the center being only 120 feet, although the radius of curvature is 250 feet, which would, with the same material at the crown, be sufficient for a semicircular arch 500 feet in span. The piers are narrow, the arches spring from a horizontal line, and sweep gently towards the center in an easy curve. This curve in the design was struck by my hand, and my assistants were directed to find what figure it was, when it was ascertained that it was a curve parallel to an ellipse. The arches, as you are aware, are not pointed arches, and it was therefore denied that the bridge is a Gothic bridge, but the arches on the tomb of Henry V. in the Confessor's Chapel at Westminster Abbey are elliptic arches, and there are examples of elliptic arches even in Norman architecture.

In such a design, then, as Westminster Bridge, it was consistent that the spandrels, cornice, and parapet, should be of an ornamental and heraldic character, and accordingly it bears in its spandrels and the panels of its pedestals the Royal Arms of the United Kingdom—those of the lamented Prince Consort; of the Prince of Wales, and the Ministers and Chief Commissioners of Her Majesty's Works who held office at the time. Instead of the massive pedestals of Blackfriars, Westminster shows a delicate and finely-worked pedestal, surmounted by the lamp standards.

To Westminster I may add the Lendal Bridge at York, of a still more ornamental character, and in which the angel which supports the Royal Arms in the center of the arch, was copied from the portrait of the Princess of Wales.

The beautiful Point du Carrousel at Paris, the work of the engineer M. Poloneeau, claims our admiration as a cast iron structure, and I need not say that Paris offers many examples of stone bridges treated in a masterly, artistic style, which do honor to the taste of the Emperor.

To determine the ornaments and mouldings for a work of the civil engineer, must depend upon great knowledge and refined taste; the buildings of the crypts, such as Westminster and Lambeth, for heavy works; those of Henry III, where admissible, according to the proportion of the arches, are most fitting; if in designs, where the Tudor arch is introduced, then the mouldings of that age. And I may here state that of all works where science and art are wonderfully combined, there has been no work before or after its time more wonderful than that extraordinary construction, the gem of Gothic architecture, the roof of the Chapel of Henry the Seventh. You must ever keep in view that the progress and perfection of artistic designs are the results of great and powerful minds, and that the employment of mediocre persons without knowledge and without taste, however wealthy may be the practitioners, must ever be a retardation to progress and discreditable to the country.

CONDENSATION IN STEAM ENGINES.

By M. E. Cousté, Government Director of Manuf.

Translated from "Annales du Génie Civil."

(Continued from page 624.)

In the surface condenser, the feed water being distilled and condensed, without mingling with cold water, there can be no back-pressure due to the gases; consequently, in the general equation (No. 5), we must cancel the terms relating to that part of the back-pressure. There is also no injection water, and the term affected by $\mu\ \Sigma$ is, therefore, equally canceled.

Equations of work in the surface condenser.—Taking into account these modifications, Eq. 5 becomes adapted to the surface condenser in the following form:

$$T\,c\,s = \tfrac{1}{3}\,S\,L\left[(P - f)\,\frac{1}{1+r}\cdot\tfrac{1}{2}\left(1 - \cos\frac{q\,(650-\theta)}{R_3\,\tau\,a'}\right) + 3f\right] \quad . \; . \; . \; . \; . \quad (13),$$

in which $\beta = 0$; for here, even more than in the injecting condenser, the heat absorbed by the condensed water may be neglected.

For metallic surfaces well cleaned we have Eq. (8).

$$a' = \frac{k}{e}\,\sigma\left(a - b\right).$$

Since a is the mean temperature of the interior surface of the condenser and varies between Θ and θ. (Θ = the temperature of steam as it enters at the pressure $\frac{P}{1+r}$) we may put

$$a = \frac{\Theta - \theta}{2}.$$

Since b is the mean temperature of the exterior surface of the condenser, if the water is rapidly circulated (a matter very essential to the good performance of the apparatus), we may admit b to be equal to the mean temperature of the water, both at the entrance and exit. As the interior surface is always covered with a very thin layer of stagnant water of condensation, and the exterior surface, notwithstanding the renewal of the water, is covered by an analogous deposit of stagnant water, protected by the rugosities of the metal, we must allow, according to Pèclet, that a' is independent of the thickness of the walls, and is simply

$$a' = k\,\sigma\,(a - b)$$

But for the co-efficient k we cannot now use the number 19.11 (in the case of a copper condenser), for a wall whose surfaces are obstructed throughout the operation, since this co-efficient is applicable only on the assumption of a perfect renewal at every instant of the water in contact with the exterior surface. We must adopt, then, the co-efficient 1.6, which results from the experiments of M. M. Thomas and Laurens, for the conducting power of copper under these conditions.

2. CASE I.—*Copper condenser with clean surfaces.*—We have, then, for the condenser with clean surfaces,

$$T\,c\,s = \tfrac{1}{3}\,S\,L\left[(P - f)\,\frac{1}{1+r}\cdot\tfrac{1}{2}\left(1 - \cos\frac{q\,(650-\theta)}{R_3\,\tau\,\sigma\,(a-b)}\,\frac{1}{k}\right) + 3f\right] \quad . \; . \; . \; . \quad (14),$$

in which expression $k = 1.6$. We shall employ k' with a value of 19.11, instead of k, when applicable to a wall whose surfaces are constantly washed by water.

3. There is between σ and θ a necessary relation, due to a periodical equilibrium, which we must assume to exist in the condenser, for we must consider the action of this apparatus from the instant at which the temperature θ becomes constant. From that instant the quantity of heat brought to the condenser by each stroke of the piston, diminished by the quantity retained by the condensed water, ought to pass through the surface σ in a time equal to the duration of a piston stroke. The quantity of heat brought by each stroke is $q \times 650$, and the

quantity to be transmitted is $q\ (650 - \theta)$. The quantity which the surface will transmit in a unit of time is $k\ \sigma\ (a - b)$; and in the time τ, or one piston stroke, $\tau\ k\ \sigma\ (a - b)$; but in taking into account the retardation expressed by the co-efficient R_s it becomes $R_s\ \tau\ \sigma\ (a - b)\ k$. Hence the equation $q\ (650 - \theta) = R_s\ \tau\ \sigma\ (a - b)\ k$; and

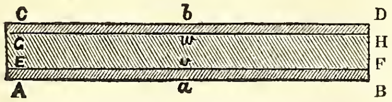
$$\sigma = q\ \frac{650 - \theta}{a - b}\ \frac{1}{R_s\ \tau}\ \frac{1}{k} \quad . \quad . \quad . \quad . \quad (14a).$$

This equation gives the minimum value σ for a given value of θ. It also clearly expresses this condition of the value of σ, that the act of condensation is simultaneous, both in its duration and termination, with the stroke of the piston. If, also, for any value of θ the surface is less than this minimum, the equilibrium will ensue at a normal temperature higher than θ. On the other hand, if the effective surface be $N\ \sigma$ (supposing $N > 1$) the work of the condenser will be less than in Eq. (14), which expresses a maximum, the effective work now being

$$T\ c\ s = \tfrac{1}{3} S\ L \left(\frac{P - f}{1 + r} \cdot \frac{1}{N} + 3 f \right). \quad (14b)$$

N being the ratio of the actual surface to the minimum surface.

4. SECOND CASE.—*Condenser incrusted on its interior surface.*—We will take the case of a plate of metal of the thickness e, covered with an incrustation of low conducting power of the thickness η, and having for a co-efficient of interior conductibility γ.



The face A B of the crust is in contact with the steam and transmits the heat to the metallic plate. This face, then, has the mean temperature a; the metallic face C D has a mean temperature b; the face E F common to the metal and the crust will then have an unknown mean temperature u. The quantity of heat transmitted per unit of time and per unit of surface of the crust is $\frac{a_{\prime}}{\sigma_{\prime}} = \frac{\gamma}{\eta}\ (a - u)$. At the moment of thermal equilibrium this quantity is equal to that which passes through the metal, having for its expression $\frac{a_{\prime}}{\sigma_{\prime}} = \frac{k'}{e}(u - b)$. Hence

$$\frac{k'}{e}\ (u - b) = \frac{\gamma}{\eta}\ (a - u)$$

Eliminating u

$$a_{\prime} = \frac{k'\ \gamma}{k'\ \eta + \gamma\ e}\ \sigma_{\prime}\ (a - b) \text{ or } a_{\prime} = \frac{1}{\frac{\eta}{\gamma} + \frac{e}{k'}}\ \sigma_{\prime}\ (a - b)$$

Substituting in Eq. (13) this value $a_{\prime}$

$$T\ c\ s_{\prime} = \tfrac{1}{3} S\ L \left[(P - f)\ \frac{1}{1 + r} \cdot \tfrac{1}{2} \left\{ 1 - \cos \frac{q\ (650 - \theta)}{R_s\ \tau\ \sigma_{\prime}\ (a - b)} \left(\frac{\eta}{\gamma} + \frac{e}{k'} \right) \right\} + 3 f \right]. \quad (15)$$

With the expression for the minimum of surface

$$\sigma_{\prime} = q \left(\frac{650 - \theta}{a - b} \right) \frac{1}{R_s\ \tau} \left(\frac{\eta}{\gamma} + \frac{e}{k'} \right)$$

or

$$\sigma_{\prime} = q \left(\frac{650 - \theta}{a - b} \right) \frac{1}{R_s\ \tau} \cdot \frac{1}{\gamma} \eta + q \left(\frac{650 - \theta}{a - b} \right) \frac{1}{R_s\ \tau} \cdot \frac{e}{k'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15a)$$

and

$$T\ c\ s_{\prime} = \tfrac{1}{3} S\ L \left(\frac{P - f}{1 + r} \cdot \frac{1}{N_{\prime}} + 3 f \right). \quad (15b)$$

5. THIRD CASE.—*Condenser incrusted on the outside.*—If the exterior face is alone covered with a crust of the thickness ε, and of the conductibility κ, we shall have expressions anologous to Eqs. (15) and (15a), in which we may replace η by ε, and γ by κ, make $e = 1$, whatever the thickness of the metal, and replace k' by k. Thus,

$$a_{\prime}' = \frac{1}{\frac{\varepsilon}{\kappa} + \frac{1}{k}} \cdot \sigma_{\prime}'\ (a - b).$$

$$T\ c\ s_{\prime}' = \tfrac{1}{3} S\ L \left\{ (P - f) \frac{1}{1 + r} \cdot \tfrac{1}{2} \left[1 - \cos. \frac{q\ (650 - \theta)}{R_s\ \tau\ \sigma_{\prime}'\ (a - b)} \times \left(\frac{\varepsilon}{\kappa} + \frac{1}{k} \right) \right] + 3 f \right\} \quad (16)$$

$$\sigma_{\prime}' = q \left(\frac{650 - \theta}{a - b} \right) \cdot \frac{1}{R_s\ \tau} \left(\frac{\varepsilon}{\kappa} + \frac{1}{k} \right) \text{ or}$$

$$\sigma_{\prime}' = q \left(\frac{650 - \theta}{a - b} \right) \frac{1}{R_s\ \tau} \cdot \frac{1}{\kappa}\ \varepsilon + q \left(\frac{650 - \theta}{a - b} \right) \frac{1}{R_s\ \tau} \cdot \frac{1}{k} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16a)$$

and

$$T\ c\ s_{\prime}' = \tfrac{1}{3} S\ L \left(\frac{P - f}{1 + r} \cdot \frac{1}{N_{\prime}'} + 3 f \right) \quad (16b)$$

6. FOURTH CASE.—*Condenser incrusted on both faces.*—Suppose a metallic plate of the thickness e, covered with a crust of the thickness η, and of the conductibility γ on its interior face (as in § 4), and with another crust of the thickness ε and conductibility κ on its exterior face (as in § 5). Let u and w be the unknown temperatures of the faces of contact E F and G H of the metal and

crusts. During the equilibrium of temperature the quantity of heat passing in a unit of time through both of the crusts and through the metal will be the same. This quantity, considered as passing through the crust A B E F, is, according to § 4,

$$\frac{a_{\prime\prime}}{\sigma_{\prime\prime}} = \frac{k' \gamma}{k' \eta + \gamma e} \cdot (a - b).$$

Considered as passing through the crust C D G H it will be

$$\frac{a_{\prime}}{\sigma_{\prime\prime}} = \frac{\kappa}{\varepsilon}(w - b); \text{ hence,}$$

$$\frac{\kappa}{\varepsilon}(w - b) = \frac{k' \gamma}{k' \eta + \gamma e}(a - b);$$

and eliminating w,

$$a_{\prime\prime} = \frac{1}{\frac{\varepsilon}{\kappa} + \frac{\eta}{\gamma} + \frac{e}{k'}} \cdot \sigma_{\prime\prime}(a - b)$$

and the equation of work becomes

$$\text{(17)}$$

$$\mathrm{T}\, c s_{\prime\prime} = \tfrac{1}{3}\,\mathrm{S\,L}\left\{(\mathrm{P} - f)\frac{1}{1 + r} \cdot \tfrac{1}{2}\left[1 - \cos. \frac{q(650 - \theta)}{\mathrm{R}_s \tau \sigma_{\prime\prime}(a - b)}\left(\frac{\varepsilon}{\kappa} + \frac{\eta}{\gamma} + \frac{e}{k'}\right)\right] + 3f\right\}$$

for the minimum of surface

$$\sigma_{\prime\prime} = q\frac{650 - \theta}{a - b} \cdot \frac{1}{\mathrm{R}_s \tau \kappa}\varepsilon + q\frac{650 - \theta}{a - b} \cdot \frac{1}{\mathrm{R}_s \tau \gamma}\eta + q\frac{650 - \theta}{a - b} \cdot \frac{1}{\mathrm{R}_s \tau k'}e \quad . \quad (17a)$$

and

$$\mathrm{T}\, c s_{\prime\prime} = \tfrac{1}{3}\,\mathrm{S\,L}\left(\frac{(\mathrm{P} - f)}{1 + r} \cdot \frac{1}{\mathrm{N}''} + 3f\right) \quad (17b)$$

7. By equations (15a), (16a), (17a), it appears that if θ be considered as a constant, and η and ε as variables, the function σ increases very rapidly in proportion to any increase of these quantities, for the equations represent a line or plane making a small angle with the axis of σ, while, as factors, the co-efficients $q\frac{(650 - \theta)}{(a - b)} \cdot \frac{1}{\mathrm{R}_s \tau \kappa}$ and $q\frac{(650 - \theta)}{(a - b)} \cdot \frac{1}{\mathrm{R}_s \tau \gamma}$ are always very large. This shows that, if we are considering a given temperature θ, the surface condenser must have a minimum cooling surface $= q\frac{650 - \theta}{a - b} \cdot \frac{1}{\mathrm{R}_s \tau \kappa}$ relative to the incrusted metal. But if we wish to omit a specific determination of the influence of incrustations we must give to the surface a much greater extent than this minimum value, and one increasing rapidly with the thickness of the scale. Hence, as I have shown in § 2, these equations express a condition of the minimum of surface, regard being had to the development of crusts; and if this minimum ceases to be obtained by reason of that development, the temperature θ will increase until the equation of the minimum is satisfied.

8. *Maximum conductibility of the metal.*—Before discussing the equations relating to the surface condenser, it may be well to examine an experimental fact, which is very singular, and appears to be somewhat parodoxical, but upon the certainty of which engineers seem to agree. According to Péclet (who has given a plausible explanation of it by observing that a slight incrustation increases the surface, by reason of the rugosities which it produces), perfectly clean metal transmits less heat than when it is slightly incrusted. We have stated that the co-efficient of the conductibility of the metal may have two widely different values, according to whether, or not, it is placed in immediate contact with the heating body on one side, and the cooling body on the other. It follows from the experiments of Péclet, that when this immediate contact takes place (as when the surfaces of the metal are continually washed, so that the film of adherent water is perpetually renewed at every instant), the quantity of heat passing through the metal in a given time is in an inverse ratio to the thickness of the metal. But if there is no such renewal of the adherent film, the quantity of heat transmitted has no definable relation to the thickness of the plate. This is a consequence of the high conductibility of metallic bodies (the fact is quite otherwise with bad conductors); that is, in the first case, the quantity is expressed for a unit of surface and time by $k'\frac{a - b}{e}$ and in the second case by $k(a - b)$. In the case of copper k' is, according to Péclet, 19.11, and according to the experiments of M. M. Thomas and Laurens $k = 1.60$.

The difference between the co-efficients k and k' will furnish an explanation of the experimental fact which we have stated. The quantity of heat transmitted by a plate in a unit of time and per unit of surface is:

(1). In the case of metal well cleaned, but not washed during the act of absorption:

$$a' = k(a - b).$$

(2). In the case of incrustation of that face only which receives the heat:

$$a_{\prime} = \frac{k' \gamma}{k' + \gamma e}(a - b)$$

(3). In the case of incrustation of that face only which emits the heat:

$$a_{,}' = \frac{k\,\kappa}{k\,\varepsilon + \kappa}\,(a - b)$$

(4). In the case of incrustation of both faces:

$$a_{,,} = \frac{k'\,\gamma\,\kappa}{k'\,\gamma\,\varepsilon + k'\,\kappa\,\eta + \gamma\,\kappa\,e}\,(a - b)$$

and for copper we have the values

$$k = 1.60 \text{ and } k' = 19.11$$

Generally a' is greater than each of three other quantities, $a_{,}$, $a'_{,}$, $a_{,,}$, and hence

$$\left.\begin{aligned} &k(a-b) - \frac{k'\,\gamma}{k'\,\eta + \gamma\,e}\,(a-b) > 0 \\ &k(a-b) - \frac{k\,\kappa}{k\,\varepsilon + \kappa}\,(a-b) > 0 \\ &k(a-b) - \frac{k'\,\gamma\,\kappa}{k'\gamma\,\varepsilon + k'\kappa\,\eta + \gamma\,\kappa\,e}(a-b) > 0 \end{aligned}\right\}(19)$$

Now it is possible that for certain values of ε and η these inequalities may change signs, and this change would be a confirmation of the fact stated. But if these inequalities change signs, they must pass through the value of zero, and conversely if they pass through the value of zero, they must change signs. Hence, if we take for the various cases above the following equations

$$\text{2d case, } k = \frac{k'\,\gamma}{k'\,\eta + \gamma\,e}$$

$$\text{3d " } k = \frac{k\,\kappa}{k\,\varepsilon + \kappa}$$

$$\text{4th " } k = \frac{k'\,\gamma\,\kappa}{k'\,\gamma\,\varepsilon + k'\,\kappa\,\eta + \gamma\,\kappa\,e}$$

we ought to be able, if the fact stated really exist, to deduce for η and ε values greater than 0.

In the second equation $\varepsilon = 0$; hence, the fact in question does not appertain to the case of incrustation of the emitting face—a result agreeing well with the explanation proposed by Péclet; for, in the case considered, no incrustation exists upon the wall which receives the heat, the absorbing surface is in no wise affected, and it can therefore give no maximum of conductibility. From the first equation we deduce

$$\eta = \gamma\left(\frac{1}{k} - \frac{1}{k'}\,e\right)$$

This value is positive for $e < \frac{k'}{k}$.

For copper $\frac{k'}{k} = \frac{19.11}{1.6} = 12$, e does not exceed 2 millim. Hence, the fact in question exists only in the case of incrustation of the face which receives the heat. The value of η resulting from this equation will depend upon the values of γ and e. We will suppose $e = 1$ millim., for the tubes of surface condensers.

In condensers the scale is a coating formed by the dust brought in by the steam, with oxide of iron, oxide or carbonate of copper, oxide of lime, magnesia, sulphate of lime, &c. Its coefficient will be intermediate between the following, given by Péclet:

Powdered brick	.14
Powdered chalk	.108
Iron filings	.157
Peroxide of manganese powdered	.163
Mean	.14

We may therefore make $\gamma = .14$, giving for surface condensers

$$\eta = .14\left(\frac{1}{1.6} - \frac{1}{19.11}\right) = .08^{\text{ m. m.}}$$

From the 3d equation we derive

$$\varepsilon = \kappa\left(\frac{1}{k} - \frac{1}{k'}\,e - \frac{1}{\gamma}\,\eta\right)$$

The external crust is formed, generally, of carbonate of lime and free magnesia, and presents some analogy to the internal crust. We may, therefore, put $\kappa = \gamma = .14$, and hence

$$\varepsilon = .14\left(\frac{1}{1.6} - \frac{1}{19.11} \times 1 - \frac{1}{.14}\,\eta\right) \text{ or}$$

$$\varepsilon = .14\left(.57 - \frac{1}{.14}\,\eta\right)$$

The nearer η approaches in value to zero, the more nearly does ε approach to $.14 \times .57 = .08$, and in proportion as η increases, ε diminishes, until it becomes zero. Therefore the thickness of the crust corresponding to the maximum of conductibility in the surface condenser cannot exceed .08 m m.

It must be remarked here that when ε and η vary from the values just assigned, the second terms in Eq. 19 decrease very rapidly. By substituting for γ, κ their value .14, these terms become respectively

$$\frac{1}{\frac{\eta}{.14} + \frac{e}{k'}} \text{ or } \frac{1}{7.14\,\eta + \frac{e}{k'}}$$

$$\frac{1}{\frac{\varepsilon}{.14} + \frac{1}{k}} \text{ or } \frac{1}{7.14\,\varepsilon + \frac{1}{k}}$$

$$\frac{1}{\frac{\varepsilon}{.14} + \frac{\eta}{.14} + \frac{e}{k'}} \text{ or } \frac{1}{7.14\,\varepsilon + 7.14\,\eta + \frac{e}{k'}}$$

These quantities measure the efficiency of the condenser, for it is by these quantities that we must multiply the extent of surface, and the difference of temperatures $(a - b)$, to obtain the respective quantities of heat transmitted in a unit of time.

9. Let us now compare Eq. 14 expressing the work of a clean surface condenser with Eq. 7 relative to the injecting condenser, resuming in the latter the co-efficient R. Replacing the cosine by its value as a function of its arc, these equations become

$$\mathrm{T}cs = \tfrac{1}{3}\mathrm{S\,L}\left[(\mathrm{P}-f)\frac{1}{1+r}\,\frac{q^2(650-\theta)^2}{4\,\mathrm{R_s}^2\,\tau^2\,\sigma^2\,(a-b)^2}\,\frac{1}{k^2}+3f\right] \quad . \; . \; . \; . \; . \; . \; . \; . \quad (14a)$$

$$\mathrm{T}ci = \tfrac{1}{3}\mathrm{S\,L}\left[(\mathrm{P}-p)\frac{1}{1+r}\,\frac{q^2(650-\theta)^2}{4\,\mathrm{R_i}^2\,\tau^2\,\Sigma^2\,(\Theta-t)^2}+3\,p\right] \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad (7a)$$

Suppose that the two condensers are equal in all respects, excepting those elements which characterize the two systems. We shall then have

$$\frac{\mathrm{T}\,c\,i-p\ \mathrm{S\,L}}{\mathrm{T}\,c\,s-f\ \mathrm{S\,L}}=\frac{\mathrm{P}-p}{\mathrm{P}-f}\cdot\frac{(a-b)^2}{(\Theta-t)^2}\cdot\frac{1+r}{1+r}\cdot\frac{k^2}{\mu^2}\cdot\frac{\sigma^2}{\Sigma^2}\cdot\frac{\mathrm{R_s}^2}{\mathrm{R_i}^2}.$$

Now $\frac{\mathrm{P}-p}{\mathrm{P}-f}$ is <1 since $p=f+f_{\prime}$; also $\frac{(a-b)^2}{(\Theta-t)^2}$ is evidently <1; k, the co-efficient for the case of metal cleaned, but having a very thin film of stagnant water upon its surface, is necessarily smaller than μ, the co-efficient of the exterior conductibility of the water; for k includes both the effect expressed by μ and the resistance of the metal to the passage of the heat. We have then

$$\frac{\mathrm{T}\,c\,i-p\,\mathrm{S\,L}}{\mathrm{T}\,s\,c-f\,\mathrm{S\,L}}<\frac{\sigma^2}{\Sigma^2}\cdot\frac{\mathrm{R_s}^2}{\mathrm{R_i}^2}.$$

Hence the work due to the retardation of condensation in the two kinds of condensers varies more rapidly than the inverse ratio of the squares of the surfaces σ and Σ, multiplied by the square of the ratio of the co-efficients $\mathrm{R_s}$ and $\mathrm{R_i}$, which is less than unity.

This inequality serves as a measure of the general superiority in principle of injecting over surface condensation through metallic plates, even without considering the effects of incrustation, which we have partially discussed. This superiority is very decided; 1st, because σ is limited by the cost of apparatus and by the space it requires, and because it is constant for a given apparatus, while Σ can be increased very considerably without increase of space or power, and can be varied at pleasure; 2d, because the co-efficient $\mathrm{R_s}$, which depends upon the friction of the steam in the tubes of the condenser and the resistance of the air in these tubes, is very small in comparison with $\mathrm{R_i}$. The principle of injection ought not therefore to be abandoned without some absolute necessity, and I shall show hereafter that no such necessity exists.

(To be continued.)

TUBE SETTING.

From "The Practical Mechanic's Journal."

Were we to go back to the commencement of the uses of tubes, when the necessity of their being fixed in series with either air, steam, or water-tight joints in tube-plates began to be understood, we should have a somewhat lengthy, but, nevertheless, interesting history of one most important detail in mechanical engineering practice to follow out. We should have to lay down in order the trials made with "tubulous" as well as tubular boilers prior to the St. Etienne experiments of 1828, to record the anxious overlooking and months of heavy toil undergone by Henry Booth, Robert Stephenson, and, we believe, Launcelot Young, in getting the "Rocket" boiler ready for the Rainhill competition; whilst in attending to this branch of tube-fixing alone any record would be but very incomplete, as it would leave out of consideration numerous other cases wherein an effectively fitted tube and plate-joint have been found essential, as in the instances of surface condensers, brewery refrigerators, coolers, *et hoc genus omne*.

Yet, however much the effective fixing of tubes has been found an engineering difficulty to carry out with close regard to economy, the methods adopted in the several instances which we have enumerated are each totally different; and compulsorily so, from the conditions governing every individual case.

In the case of a steam-boiler, the joint is required to remain tight and secure under various and, more usually, very high pressure of steam, at correspondingly intense degrees of temperature; to resist which it is necessary to insure almost atomic contact between the metal of the tube and tube-plate. Thus, expedients are resorted to, whereby intense permanent local pressure to maintain the imperative degree of metallic contact may be derived. In the case of a high pressure boiler (locomotive, for example, with the spring balance set to allow the safety-valve to blow off steam at from 120 to 150 lbs. pressure per square inch), it is almost impossible to secure by mechanical appliances, in every case, that degree of closeness of the joints so that all of them in any given boiler will be tight; wherefore it is no unusual thing to find that after all the care of the boiler-smith has been used by driving conical drifts, and followed up by the (until lately) nearly universal method of driving in conical cast iron expanding ferrules, some 40 per cent of the tube joints leak. But a boiler is *self-curative*, and we have often been on a locomotive engine running its trial mileage, with steam and water bubbling and hissing out from the tube joints at both fire-box and smoke-box ends to a highly injurious degree, yet we have examined the same boiler a few days, and sometimes a few hours afterwards, and found the leakage had stopped. But in the case of surface condensers, refrigerators, and so on, the effects of high temperature and rapid corrosion through the pressure of a corroding (*i. e.* oxidizing) liquid passing very rapidly over the leaky parts of the metallic joint do not obtain; therefore certain kinds of elastic packing, which remain uninjured at low temperatures have come into use, either of hemp, flax, india-rubber, or other fibrous or expansive material; and these have been, and continue to be, employed in a variety of forms.

In the present paper we desire more particularly to direct attention to the methods and tools employed for fixing tubes in steam-boilers; and in every case, except in one very important example with which we are acquainted, it is well here to state that such fixing is effected by *expanding* the tube end to fill the hole made in the tube-plate; whilst in most cases of surface condensers and refrigerators the tightness is secured by the *compression* of some elastic packing between the outer surface of the tube and the inner surface of the hole or recess in the tube-plate.

In regard to the fixing of tubes in boilers, the expansion of the tube end to fit the hole in the tube-plates was for a long time universally effected by the mere driving, by hammer, of a conical drift into the tube; and as the holes in the tube-plates were bored parallel, the tubes could not by this method be made to thoroughly fill the holes except at the extreme outer ends, or where the drift was of maximum diameter; nevertheless, in moderately pressed, and, indeed, we have known many cases of very highly pressed boilers, this method for a long time was the best known—additional tightness of the joint being secured by caulking the tube end and plate whilst the drift was inserted.

Afterwards, to increase the efficiency of the foregoing method of fixing by drifting, cast-iron truncated conical ferrules were introduced, so as to maintain a constant outward pressure of the tube end into the tube-plate hole; but these were found to be sources of trouble, producing difficulties in the way of cleaning the tubes, also constituting prominences at the smoke-box end, whereby small pieces of coke, coal, and ash, which, had the tubes been free from such obstruction, would have passed through them, were retained; therefore, in many cases wherein the cast iron ferules had been used, they were abandoned, and return was made to the fixing by drifting and caulking alone.

In a steam-boiler a well-fitted tube serves two purposes, namely, the provision of heating surface, and it also acts as a longitudinal stay; this latter feature has, however, in many designs for tube-fixing been entirely over-looked, more especially by French engineers, several of whom have proposed plans by which the tubes may be removed for both interior as well as exterior cleansing and scraping; but these devices are generally of that order which incurs the expense of very costly fittings, besides taking up so much more room in the tube-plate that the effective heating surface of the boiler is diminished, through the mere impossibility of putting in so large a number of tubes; and the tubes, when applied by such methods, constitute but very inefficient stays, and for this reason, we believe, have never been widely applied.

As to the importance of some not yet devised method by which the presently admissible number of tubes in a multitubular boiler may be maintained, and the tubes themselves rendered capable of expeditious removal and replacement, there cannot be a question; and the discovery of such a method promises a sure and certain reward to the inventor. For, at present, when a tube has to be removed, it is altogether useless for being replaced in the same boiler, because the ends are generally corroded into chemical unity with the tube-plate, and are bent and battered about into various tortuous forms, besides being split in the separation. Nor is this all the injury done, for it frequently happens that the hole in the tube-plate is thrown so much out of form by rust and cutting, that it has to be re-bored—that is, enlarged—to render it fit for receiving a new tube. The loss incurred through the destruction of the tube ends was felt to be so serious in one factory with which we are acquainted, that a few years ago the superintending engineer proposed to employ a knife-cutter, working in a lathe, for the purpose of squaring off the ends of the injured tubes; and he further proposed to use them again by putting on a short length of tube at one of the ends, jointing the two together by brazing over an interior ferrule. We are not sure whether the proposal was carried out extensively, and we even doubt if it could be economically and with general success adopted, for many practical difficulties appear to us to lie in the way. Of late years some of the defects to which we have alluded have been partially overcome by the introduction of tools for cutting the ends off the tubes before they are removed.

To return, however, now to consider the methods and tools employed for expanding the ends of the tubes outwards so as to fit the tube-plate holes.

Some years ago, when the necessity for doing this in a more rapid manner than by the "hammer and plug" method was seriously felt, several forms of expanding mandrels cropped up, some actuated by screw pressure, and others by hydraulic pressure; but all these have now yielded to those forms of tube expanders in which the expansion is produced by the stretching action of a series of rollers revolving inside the tube and pressed outwards by means of a central cone. Until quite recently the tool made by Dudgeon, of New York, was undoubtedly the most rapidly acting, and in all respects the best tool for the purpose which engineers possessed. Yet Dudgeon's expander has some defects, amongst which we may mention the impossibility of producing a parallel expansion of the whole length of the expanded part of the tube, so as to fit perfectly the hole in the plate, except when the central taper mandrel is driven fully in, so that the parallel upper end of it bears throughout their entire length upon the rollers; and whilst the tube-plate holes may sometimes be of size to enable the mandrel to be driven in so far, yet it can only in few cases be so.

Dudgeon's expander, although for a year or two now pretty largely used, must, we are disposed to think, give place to another form of expanding instrument introduced by Mr. Thomsom, engineer, of Glasgow; and although only a few months before the public, this instrument has been made and sold in very large numbers.

Like Dudgeon's instrument, Thomson's also consists of a central cone and surrounding rollers, Dudgeon's being *parallel*, whilst Thomson's are truncated cones. In Thomson's expander the taper of the roller lies opposed in direction to the taper of the mandrel, and the ratio of taper on each being equal, necessarily insures that points in the circumference of the rollers lie parallel to each other; thus producing a parallel expansion of the end of the tube so as to thoroughly fill the hole in the tube-plate. Thomson's expander being the most recent, we have thought it desirable, in order to give additional clearness to our previous remarks, to illustrate by woodcuts.

The instrument is made in several forms, two of which are shown at figs. 1, 2, 3 and 4; figs. 1 and 2 being an elevation and plan of one arrangement, figs. 3 and 4 a vertical section and plan of another arrangement. In figs. 1 and 2 the expanding rollers *a* are held by circularly dove-tailed heads *b* in dove-tailed radially situated recesses *c* formed in the body A, so that they cannot fall or be pulled out. When that part of the instrument which secures the rollers *a* is placed within the end of the tube to be expanded, the nut B is tightened on the screw C against the head of the body A. This has the effect of drawing the large end of the central conic mandrel inwards, and it therefore presses out the rollers *a* against the interior of the tube. When they are thoroughly tightened so as to press the tube against the hole in the tube-plate, the whole instrument is rotated in the tube by applying a winch-handle or wrench to the required end *f* of the central spindle. When the expansion of the tube has been effected, the instrument is removed by loosening the nut B, thus allowing the central spindle to be pushed inwards, and therefore releasing the pressure on the cones. In the other form of the instrument, shown at figs. 3 and 4, the action is the same as in the preceding, but the cones are held in place by the flexible steel or elastic ring *d*, which embraces recesses in their necks.

Instruments founded on similar construction to the expander have also been introduced by Mr. Thomson for cutting tubes, also for withdrawing both ferrules (when these are used), as well as the short pieces of tube from the tube-plate, without injuring the holes therein. The tube cutter is shown at fig. 5 in elevation, and at fig. 6 in

Fig. 1.

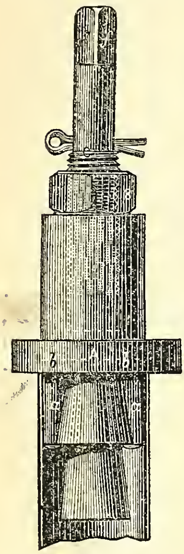


Fig. 3.

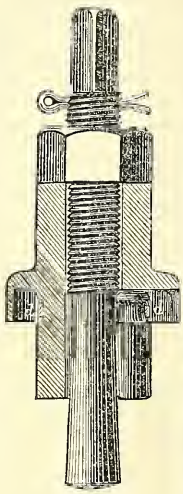

Fig. 5.

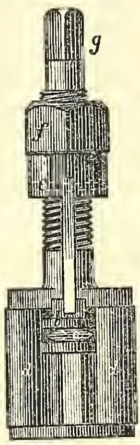

FIG.2.

FIG 4.

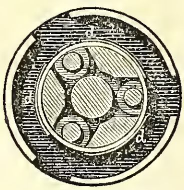

FIG.6.

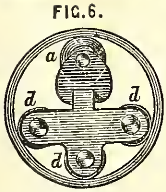
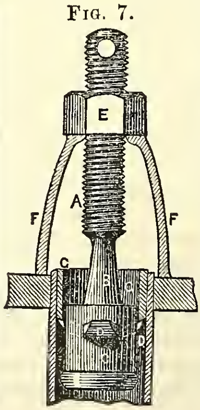


end view. The cutting disc *a* is carried on an axis in the carriage *b*, which is hinged by a bar to the body of the instrument at *c*. The body also carries rollers *d*, and in the center the taper guide *e*; and as the carriage *b* and the cutter *a* are forced downwards upon the guide *e* by the nut *f*, the cutting disc *a* is forced out against and into the metal of the tube to be cut. By turning the instrument round with a wrench applied at the squared end *g*, the disc *a* being forced out cuts an even indentation all round the interior of the tube, two or three revolutions being sufficient to cut ordinary boiler tubes completely through.

The tool for withdrawing ferrules or the cut-off ends of tubes from tube-plates is shown in elevation at fig. 7. It consists of a spindle A having a cone B formed at one end. A hollow cylinder C, fitted with a number of claws D, is fixed around the cone B, so that by tightening the nut E against the bridge F the cone B is drawn backwards; thus expanding the claws D so as to catch against the inner edge of the ferrule G, and by continuing to tighten the nuts E the ferule G is drawn out.

We have before merely hinted at one exceptional mode of securing boiler tubes, based upon the reverse foundations of what we have heretofore more especially considered; that is, the plan of M. Berendorf, of Paris, and which, we believe, has been pretty largely used by the firm of Cail & Co. of Paris. The plan consists in boring the tube-plates with holes of larger diameter than the tubes to be inserted; in the annular space which obtains around the tube when it is inserted, a double-coned ring is inserted; this, on being driven in, acts with its outward conical face, by filling the hole in the tube-plate, and the inward hollow cone becomes compressed around the tube end. Berendorf's plan is said, in certain cases, to have answered well, and we know that it is at present being looked upon attentively by boiler-making firms in the north. Our opinion of the method is that it may answer well for boilers not worked above a medium steam pressure, but it is quite evident that tubes when so fixed cannot act with nearly so much efficiency as stays, as when secured in the tube-plates by expansion outwards; and

Fig. 7.



although the system may afford more facility in the removal and replacement of the tubes, which we fully admit, still it is quite clear that the heating surface of the boiler is reduced, on account of the space taken up by the rings preventing so large a number of tubes being inserted in any given dimensions of tube-plate.

When reviewing certain methods of fixing tubes, in the foregoing part of this paper, we confined our remarks more especially to boiler-tubes. We now propose to consider what has been done to effect the same object in surface condensers.

The methods which have been at different times employed for fixing condenser-tubes may be divided into three general heads:

A. In which the packing used is metallic.

B. By means of fibrous packing.

C. By means of elastic media such as india-rubber.

Method A was proposed and first used by James Watt for fixing the tubes of his surface condensers, which he at an early date used in preference to the injection condenser. We are not informed accurately (so far as we have been able to ascertain) as to the precise details of the method by which they were fixed, but as their upper and lower ends were secured in cast iron boxes, we imagine that they must have been expanded by drifting. Similar condensers, so far as we can learn, were constructed on the Clyde by Mr. David Napier, about 1820–21, and about the same period Brunel patented another form of condenser.

Very little importance was, however, achieved with the surface condenser until 1831, when Samuel Hall turned his attention to the subject, and eventually produced such excellent results.

Fig. 8.

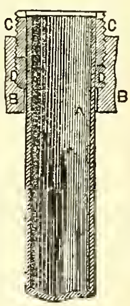


Fig. 9.

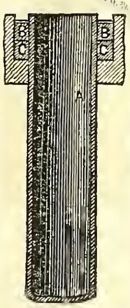

Fig. 10.

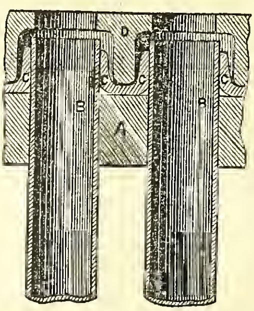

Fig. 11.

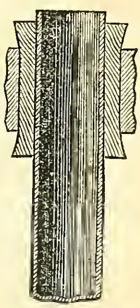

His mode of fixing is shown at fig. 8, which is a longitudinal section of a tube A fixed in the condenser tube-plate B. The hole in the tube-plate B is recessed to a considerable depth, the recess forming an annular space surrounding the tube when in its place, and it is tapped so as to receive the short screwed ferrule C, which, being screwed down, compresses the ring of hemp D into the lower part of the recess. By this means the tube is not only very effectually held in the plate, but at the same time it is allowed to expand and contract freely without straining either the plate or itself, whilst, by merely withdrawing the ferrules at either end of the tube, and picking out the hemp packing, the tube is left free for removal. We must remember that this arrangement of Hall's was the first which was found practically successful. There is no record of a surface condenser having been successfully employed in a sea-going steamer at any previous date.

As we are not at present discussing the merits and construction of condensers themselves, but one particular detail only, next in order we find Spencer's method, shown at fig. 9. This consists in recessing the tube-plate around each tube A to the depth of .125 to .187 of an inch in width, and compressing into them two or more (but usually two) india-rubber rings B C, which are put in sufficiently tight to prevent leakage when the pressure is on the outside of the plate. Then follows Sewell's; it is shown at fig. 10. This plan of fixing condenser-tubes is perhaps the most complicated of any introduced. The tube B projects some distance beyond the tube-plate A; over these projecting portions a sheet of india-rubber, formed so as to fit over the whole of the tubes, is placed. This sheet is necessarily made in one entire piece, of the same size as the tube-plates, and in it holes are formed to correspond in pitch with that of the tubes; but the holes themselves are slightly less in diameter than the tubes, so that on being placed over them the india-rubber turns up in a cup-like form round the exposed ends, as shown. Over the india-rubber sheet is an outer plate D perforated to correspond with the tubes; it is recessed, as shown, so as to pass over the tubes and surround the india-rubber cups, at the same time leaving room for the tubes to expand and contract freely when the plates are screwed together. The diameter of the holes in the outer or covering-plate is nearly the same as the interior caliber of the tubes themselves, and it serves two purposes, namely, of keeping the india-rubber sheet close against and on the ends of the tubes, at the same time preventing the tubes from working out of the plates. This method, although the most expensive, has, we believe, been pretty largely adopted of late years, but we know that some engineers do not think favorably of it.

Allen's method is shown at fig. 11; it consists merely in inserting a wooden ferrule A into an annular space in the tube-plate which surrounds the tube; this, on being driven in, becomes compressed, thereby filling the hole, and at the same time firmly holding upon the tube; but before being put in, the ferrules are first squeezed in a compressing machine.

Howden's method is shown at fig. 12. In this case the hole for receiving the tube is reduced to a depth equal to about three-fourths of the thickness of the tube-plate, and into it a short length of plaited cord is compressed, the cord being very easily and quickly inserted by means of a tool revolved in the recess by a hand-brace; this system is, perhaps, the cheapest and simplest yet devised, and is, we understand, coming into use on board of several steamers.

The last, and, so far as we can learn, a very effectual method of fixing condenser-

Fig. 12.

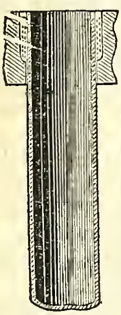

Fig 13.

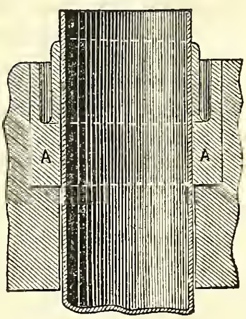


tubes is that introduced within the last few months by Marshall, of Leith; it is shown at fig. 13. In this example the recess surrounding the tube is filled with an india-rubber ring A, which ring has a deep annular space formed in it, into which the water passes, having the effect of forcing the outer lip of the ring against the tube-plate, and the inner lip against the tube, thereby constituting an effective joint on both sides. Marshall's plan is being already introduced on the Clyde as well as at Leith, and the North British Rubber Company have commenced the manufacture of the rings.

We have now brought together all the more important modes of fixing surface condenser tubes, and as we shall on a future occasion probably refer at length to surface condensers themselves, we reserve further remarks on the subject at present.—V. D.

The Flow of Elastic Fluids through Orifices or Pipes.—In order to determine the number of cubic feet of steam or air, or other gas, which will be discharged through a given orifice in a given time, it is necessary to ascertain the velocity of issue. In no other way can the problem be solved, except by experiments with vessels of known capacity, from one of which the air, steam, or gas flows to the other. Such a solution is, for reasons on which it is not necessary to enter, practically beyond the reach of most men; and it has already been tried by many, with results which have enabled a general law to be laid down, to which law we shall come presently. If the velocity is known all the rest follows easily enough. Let us suppose the orifice in the side of a boiler to be one inch square. A cubic foot of steam contains 1,728 cubic inches. We may suppose this cubic foot of steam all contained in a column or bar 1,728 in. long and 1 in. square. Let one end of this bar be brought opposite the orifice and the work of expulsion begun; then it is obvious that before the whole cubic foot of steam is discharged, a column of steam 1,728 in. long must be passed through the hole. Now, if the velocity of efflux is 1,728 in. per minute, then one minute of time will be required for the escape of one foot of steam. If it have a velocity of efflux of 1,728 ft. per second, then the orifice will discharge one cubic foot per second, and so on. And this law is totally independent of the pressure or weight of the steam. As the pressure increases, the *velocity* of discharge will increase in a certain ratio to be presently explained; but the pressure will not affect the fact that the *velocity of discharge in inches per second*, multiplied by the area of the orifice in square inches, and divided by 1,728, will give the discharge in cubic fees per second.*

We have said that the velocity is regulated by the pressure, but this fact only holds good for each particular fluid. Speaking

* When a discharge of water, steam, gas, or other liquid or fluid takes place through an orifice in a thin plate, a certain contraction takes place in the issuing column which reduces the amount of discharge below that proper to the actual area of the orifice, but it is needless to do more than mention the fact here. It is quite unnecessary to complicate a statement which we wish to make as simple as possible, by further reference to the *Vena Contracta*.

comprehensively, the velocity of discharge depends on the density as well as the pressure of the fluid; the lighter the fluid the greater will be the discharge. Thus, hydrogen will issue more rapidly under a given pressure through a given orifice than will atmospheric air under the same conditions of pressure and orifice. If our readers have followed us thus far, they will be able to comprehend the nature of the law determining the velocity of discharge under given conditions of orifice and pressure. But before giving this law it may be as well to explain, that any body falling freely under the influence of gravity has a progressively accelerated rate; the velocity being in England and similar latitudes such that 16 ft. 1 in. will be traversed the first second, 48 ft. 3 in. in the next second, 80 ft. 5 in. in the the third second, and so on. The velocity of a falling body at any distance from the point where it started, may be found by multiplying the square root of the height passed through in feet by $8\frac{1}{24}$, the product being the velocity in feet per second. Thus, a bullet has been suffered to drop from the top of a tower 100 ft. high; what is its velocity at the moment of touching the ground? The square root of 100 is 10, and 10 multiplied by $8\frac{1}{24}$ gives 80.042 ft. as the velocity. Our non-mathematical readers will now be in a position to understand the law regulating the velocity of efflux of elastic fluids, such as steam, under pressure, which may be thus stated: *Elastic fluid flow into a vacuum with a velocity the same as that which a body of the same density would acquire in falling through a space equal to the height of a column of steam or gas of the given pressure.* Let us suppose that we are dealing with steam of 45 lbs. on the square inch, and the orifice of discharge has one square inch of area. Let us further suppose that a column of steam stands on a valve temporarily closing the orifice. What height must the column of steam one inch square be to weigh 45 lbs.? Avoiding fractions, nine cubic feet of such steam will weigh 1 lb.; therefore, our column of steam one inch square must contain 9 × 45, or 405 cubic feet of steam; and multiplying 405 by 1,728, we get 699,840 as the height in inches, or 58,320 as the height in feet of our column of steam.* The square root of 58,320 is 241.5 nearly, and this multiplied by $8\frac{1}{24}$, or 8.042, gives 1,942.14 ft. per minute as the velocity with which steam of 45 lbs. pressure would issue into a vacuum.

It is here necessary to explain that to avoid the introduction of a multiplicity of figures, we have omitted several fraction, and, therefore, the velocity we have given above is too low, but this in no way affects the principle of the arithmetical process we have described. Any of our readers mastering it will be able to calculate for themselves the velocity with which elastic fluids flow into a vacuum. The calculation, as we have worked it out, is, however, laborious, and for the benefit of such of our readers as understand logarithms, we give the following comprehensive rule for finding the velocity of discharge: Add 4.29 to the pressure in pounds per square inch; deduct the logarithm of this sum from the logarithm of the pressure; to one half the remainder add 3.3254, and the natural number of this sum will be the velocity in feet per second.† The difference between the velocities due to any two pressures is the velocity with which steam or air will flow into the lower pressure. Thus, if the pressure in a cylinder is 20 lbs., while that in the condenser is 5 lbs., at what rate will the steam flow from the former to the latter? The velocity proper to steam of 5 lbs. pressure is 1,552 ft. per second, while that proper to 20 lbs. is 1,919, and 1,919—1,552 gives 367 ft. per second as the velocity of the exhaust.‡

In the earlier portion of this article we stated that the actual area of the column of discharge was less than that of the orifice through which it flowed, and it is now time to say that this fact materially modifies the results of such calculations as the foregoing. Moreover, account must be taken of the frictional resistance due to the sides of pipes or tubes through which the fluid flows. On this latter subject there is considerable diversity of opinion; the subject has been keenly discussed once in our correspondence columns, and we shall not be surprised if it be discussed again. Meanwhile we cannot better conclude this article than with the following rule, extracted from "Bourne's Treatise on the Steam Engine," and regarded by many engineers as one of the best yet made on the subject. It refers to the flow of steam through a straight pipe of uniform diameter, and its relation to the

* This is an approximation only. The true volume of 1 lb. of steam at 45 lbs. total pressure is 9.000216 cubic feet.

† Sewell.

‡ These velocities have been calculated by the last rule.

rules we have laid down will be readily traced: "To the temperature of the steam in degrees Fah. add the constant 459, and multiply the square root of the sum by 60.2143; the product is the required velocity." All enlargements and contractions, and all bends or elbows, will reduce the velocity, but there is no trustworthy formula in existence which will enable us to determine exactly how much in any of the particular cases which may suggest themselves to our readers."—*The Engineer.*

BIRMINGHAM.—None, caring to trace the growth of the "work-shop of the world," need necessarily go back to the time, less than a hundred years ago, when letters were addressed "Birmingham," (or, often, Bromwicham), near Walsall," the latter being the nearest post town. The population of Birmingham, now upwards of 350,000, has doubled since 1841, and is five times what it was at the beginning of the century. Even those who have never been within a hundred miles of the place, know the general nature of its manufactures, but few are aware how these have increased in extent and variety of production. Almost exclusively a manufacturing town, Birmingham may nevertheless be said to have no cotton, woolen, flax, or silk factories, no blast furnaces or forges, no steel converting works, no work-shops for making locomotives, engineers' tools or textile machinery, no sugar refineries, paper mills, tanneries, breweries (except upon a small scale), in fact, none of those great distinctive industries which make Manchester, Leeds, Sheffield, and, in a less degree, Newcastle, Glasgow, Bristol, and other great manufacturing towns, what they are.

But there are large factories in Birmingham, where hundreds of work-people are employed in making pins, steel pens, umbrella tips, tacks, indeed the smallest articles in the largest (or, at least, in bewildering) numbers. Steel pens, for example, which once cost a shilling each, are now sold, and of far better quality, for a shilling a gross, and, of these, single establishments make from 200 to 300 millions each yearly. These are the *minutiæ* of manufactures, but there is a single establishment employing a thousand work-people, which produces a thousand million of wood screws yearly. Nearly as large a number are employed, at a single factory, in making bolts and nuts, and, besides these, iron hoops for cotton bales. And in the pen factories, including Gillott's and Mason's, in Nettlefold and Chamberlain's great screw factory, at the works of the Patent Nut and Bolt Company—nearly everything is done by machinery. The immense stride made in the manufacture of Birmingham goods during the last comparatively few years has been due to the introduction of machinery, worked in large factories, under perfect organization; whereas, previously, masters let out metals, or part-worked goods, to work-people who took them home and completed them by hand. The Birmingham gun trade was revolutionized by the erection of the immense small arms factory at Small-heath, which contains the most perfect gun-making machinery of the Enfield kind.

Of Birmingham buttons, gold and "brummagem" jewelery, nondescript hardware and knick-knacks, we cannot pretend to speak with knowledge. But turning to the larger industries, there are the historical engine works at Soho, besides smaller engine works in town; the very extensive railway carriage works of the Metropolitan Railway Carriage Company at Saltley, and Messrs. Brown, Marshall and Co.'s railway carriage works in the vicinity; Messrs. Chance Brothers' great glass works, Winfield's large establishment for making iron bedsteads and brass work, Everitt's, Webster and Horsfall's, and Cornforth's wire mills, Elkington's magnificent electro-plate works, Muntz's yellow metal works, Lloyd's and the Imperial tube works, the Stephenson copper and brass tube and roller works, Tangye's and May's engine and machine works, Morewood's galvanizing works, Piggott's and Horton's gasholder works, etc., besides the old copper mint at Soho, enameling works, manufacturies of *papier maché*, swords, files, etc., all representing distinct industries, in each of which, perhaps, two or three, or in other cases forty or fifty establishments are engaged.

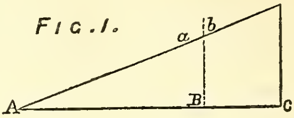
It is not, perhaps, to be lamented that Birmingham no longer produces those great works of engineering construction which she once did in the days of Fox, Henderson & Co. Their old works, the London Works, now the property of the Patent Nut and Bolt Company, turned out all the ironworks of the Crystal Palace of 1851, the great station at Birmingham, still the largest, under one roof of a single span, in the world, the Paddington Station, and the great suspension bridge over the Dneiper, at Kiev, in Russia, probably the finest individual work of its engineer, Mr. Charles Vignoles.

Birmingham is a little too far from a sea port for the cheapest transit of heavy manufactures intended for shipment abroad, but its railway and canal facilities for inland communication are unexcelled. It is a healthy town, on elevated, gravelly, or sandy soil; the latter, when in its natural state, growing a profusion of broom (Saxon *brum*, whence the name of the town), and the death-rate is much lower than in Manchester, Leeds, Sheffield, or Liverpool. There are few underground habitations—cellars—and one man in Birmingham occupies as much ground as two in Manchester, or three in Liverpool. It is only a wonder that so wide-stretching a town has not long since been tramwayed in all directions, a fact only accounted for, perhaps, by its local railway facilities. Nor is it easy to understand why some of the heavier branches of forging, steel melting, wheel making, locomotive engine building, etc., should not have yet settled there, unless it is that the business is overdone, or that Staffordshire iron, so well known for its good quality, is somewhat more cheaply worked up elsewhere.—*Engineering.*

THE MEASUREMENT OF HILLS.

From the "Building News."

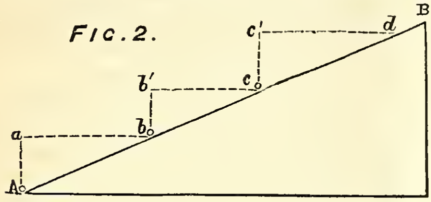
It is seldom, that a base line of any considerable length can be measured without it being necessary to make some allowance, either mechanically or by calculation, for the sloping and irregular contours of the ground. The necessity for this becomes more apparent as the surface of the ground departs from the plane of horizontality, as the greater the angle of inclination the greater will be the difference between the false and the true, or the inclined and horizontal measurement. There are various methods of arriving, at the true horizontal measurement of sloping surfaces, and the degree of accuracy to which the survey is to be carried, must in all cases determine which the surveyor will employ. It is scarcely necessary to mention that the true distance will always be less than the apparent one, and, therefore, when calculation is used, there will always be a reduction to be made. An experienced surveyor will be able to tell pretty well by the eye the allowance to be made in the majority of instances when only approximate accuracy is demanded, and the question becomes reduced to taking the next measurement or chain's



length, not from the end of the former, but from a point obtained by making the proper allowance. The diagram in fig. 1 will render this operation perfectly clear, but it is one that the young surveyor will do better not to attempt to carry into practice. We shall give a method by which the same result can be arrived at by means more suitable for a beginner. In fig. 1, suppose the chain to be stretched upon the inclined surface of a hill and extend from A to *a*, but the real horizontal measurement to extend from A to B. The point B where the chain A *a* will intersect the horizontal is found by taking A *a* in the compasses and sweeping a circle until it touches the horizontal line A C in B. If the line B *b* be projected at right angles to A C it will intersect the surface of the ground at *b*, so that the true distance to be measured along the slope by one chain's length, is not A *a*, but A *b*. From the appearance of the slope the practiced surveyor makes an approximate estimate of the distance *a b*, and the next chain's length is measured consequently not from *a* but from the point *b*, and so on, as often as may be required. The same process applies to the case of a descent as well as that of an ascent, but it is rather curious that it is invariably more difficult to arrive at a correct approximation of the rate of inclination when descending than ascending a slope. We do not attempt to offer any explanation of this somewhat curious fact, but our own experience, as well as that of numerous old and practiced hands, have confirmed the veracity of it.

The explanation of the method by which the distance *a b* in fig. 1 is estimated, will serve to indicate a mechanical mode of arriving at the same result. This latter is preferable, when carefully performed, to that given in fig. 1, and may, moreover, be accomplished by any beginner. It should not, at the same time, be repeated too often consecutively, as of course, small errors creep in at every step, which ultimately would become seriously appreciable. Let A B in fig. 2 be the sloping ground to be measured horizontally. In performing this operation we advise the surveyor to do part of the chaining himself, that is, to take the place of the "follower." If he leaves it to the chainmen to do, he may be sure that it will not be done well, as it is an operation requiring some nice and delicate manipulation. Briefly, the principle consists in taking up the chain in short lengths and holding one end vertically over the starting points, while the other

FIG. 2.



is fixed or held firmly down. In the figure let the surveyor be supposed to stand at A, with the end of the chain held vertically over the point A, by means of a plumb line and bob. In the meantime the "leader" has hold of the twenty-fifth link, suppose, which he fastens down in the proper direction at *b*; the surveyor then slacks the end of the chain, advances to the point *b*, takes up the chain carefully at the twenty-fifth link, leaving the pin in to mark the spot, and holds it over the point *b*, or, in technical phraseology, "plumbs" it over the point *b*. The "leader" has advanced to the fiftieth link, which he has fixed at *c*, and the operation proceeds in a similar manner to *d*, and until the summit of the incline is surmounted. The chain must be well stretched between the points at *b'c*, *c'd*, etc., in order to render the deflection inappreciable, so that it is preferable to take short lengths at a time, instead of long ones, although the former may demand more trouble. The steepness of the slope will also regulate the distance between the successive points of measurement, as the chain can only be raised a certain height by hand, and it is absolutely necessary that it be maintained as nearly horizontal as the circumstances of the case will allow. If this mechanical reduction of the inclined to the horizontal measurement be carefully performed, the result will be a very close approximation to the true distance. In order to get over the ground as quickly as possible, young surveyors are very apt to make the distances between the points of measurement much too long, and consequently the "sag" of the chain induces errors that might otherwise be avoided with facility. Should the hill be very short, the incline may be measured very expeditiously in the manner described by means of a good tape, provided there is very little wind blowing.

Having described the two approximate methods of reducing the sloping to the horizontal measurement, it now remains to indicate the more exact means of obtaining the same result. It is hardly necessary to observe that in large and important national and trigonometrical surveys approximate methods cannot be employed, but all the operations must be performed with the most minute accuracy. A glance at at fig. 1 will point out that there are three sides in the triangle A *b* B, one only of which is known. By the rules of proportion, as well as of equations, when one of these indeterminate quantities is to be determined, two must be given in order to solve the question. In the triangle A *b* B, the distance A *b* is given and if B *b* were known, the horizontal distance could be ascertained, since $(A\,b)^2 = (A\,B)^2 + (B\,b)^2$, or making $A\,b = x$; $A\,B = y$, and $B = z$, we have for the value of A B, $y = \sqrt{(x^2 - z^2)}$. But B *b* is the difference of level between the points A and *b*, which can be readily obtained by that branch of surveying which treats of the operations of leveling. As this will be subsequently treated of in its proper place we shall not now enter further into the question. It will be manifest that if instead of the distance B *b* being known, the angle of inclination or the angle B A *b* were ascertained, the problem could be solved equally readily. Suppose, for instance, a certain number of feet were measured along the slope in fig. 1, from A to B, the correct horizontal measurement of which was A B, but which has to be determined; let A B = N′, A *b* = N, and Θ equal the angle of elevation B A *b*. By the rules of trigonometry for solving right-angle triangles we have $N' = N \times \text{cosine } \Theta$, consequently the difference between the horizontal and the sloping measurement varies as the cosine of the angle of elevation, or, in plain terms, with the slope of the ground. The difference between these two measurements, or what is called the "reduction," is evidently equal to (N—N′). As an example, suppose N or the distance A *b* in fig. 1 to measure 100 ft., and the angle B A *b* 15°, what is the value of the correct horizontal measurement A B, and of the reduction (N—N′)? By the rule we have $A\,B = A\,b \times \text{cosine } 15° = 100 \times 0.96592 = 96.592$ ft. The reduction, therefore, is equal to (100—0.96592) = 3.408 ft. The correct distance to be entered in the field book from A to *b* is 96.592 ft., but if there is no necessity for noting the point b' on the plan, the simplest method will be to add 3.408 ft. to the 100 ft. already measured, and commence the next chain's length from that point. In other words, 100 ft. on the horizontal measurement equals 103.408 ft. on the sloping surface. From the formula and example we have given, it is readily perceived that tables can be constructed giving the reduction to be made, or the difference between the horizontal and sloping measurement for different angles of inclination. In the following table is shown the number of feet on a sloping surface inclined at various angles that corresponds horizontally to 100 ft. measured along the given slope, and also the reduction to be made for every chain's length or 100 ft. measured along the slope:

Angle of slope in degrees.	Value of 100 ft. measured horizontally.	Difference or reduction.
3	99.862	.138
6	99.452	.548
7	99.254	.746
10	98.480	1.520
12	97.814	2.186
14	97.029	2.971
16	96.126	3.874
18	95.105	4.895
20	93.969	6.031
23	92.050	7.950
27	89.100	10.900
30	86.602	13.398

If the slope continue uniform, and there are not any fences or other objects to be noted in the field book, the chaining can be continued as far as may be considered desirable, and the results in the third column given in the table multiplied by the number of chains measured. The product will give the total reduction or difference to be allowed for.

The Ellershausen Process.—We have not yet received the analyses, complete, that we promised to publish. But we are prepared to state, from the results of other and more extended experiments, that this process is highly successful and valuable. It is not so radical and revolutionary as at first supposed, but it is a decided improvement upon a preparatory process in puddling, the results being an improvement in the quality of the product, and a decided and uniform economy in its production. We shall give details in due time.

HEATING BUILDINGS BY GAS.

From "The Engineer."

The use of gas as fuel has been tried to a considerable extent in France and other countries, but the progress has neither been rapid nor very satisfactory; one reason of this lies, perhaps, in the imperfection of the modes of combustion, although something has been done of late to remedy this; another is the natural hesitation of the directors of gas works to keep pressure on their gasometers all day for a small supply.

Still enough has been done to supply a certain amount of information on the economical part of the question, both as regards gas cooking apparatus and stoves for churches and other large buildings. The average consumption of the cooking stoves in use in France which consume a mixture of gas and air is found to be as follows:—For a large fire, 260 liters per hour; for a moderate fire, 140 liters per hour; for a small fire, 50 liters per hour. When the stove is used, what the French call *pot-au-feu*, it is found that it is sufficient to keep up a large fire for about twenty minutes only, after which the gas may be turned down and the cooking completed with a very small fire. Taking the average duration of this kind of cooking at four hours, and the cost of gas at 30c. per cubic meter—the present price in Paris—the consumption amounts to 1,040.20 liters, the expense of which is 31c. 20, or little more than 14d. The cleanliness and handiness of gas as fuel, and the great economy arising from its instantaneous lighting and extinction, give it, *in the hands of careful persons*, a great advantage over charcoal, with few of its inconveniences—one of which is the impossibility of using it for broiling without a special arrangement, as the smallest quantity of fat falling upon heated charcoal fills the house with stifling fumes.

In a coal-using country, however, like England, the use of gas for the heating of apartments, and especially large buildings like churches, is of more importance than its application to cooking; and considerable improvement has been made of late in France in apparatus for the warming of ordinary rooms, to which we shall shortly have to refer more particularly.

The most important results yet produced refer to the heating of churches, which has been essayed on a large scale at Berlin. The method generally adopted is that of placing a horizontal gas-pipe with three jets within a stove made of sheet iron, and over the gas-jets a piece of brass wirework, of which the openings are not more than $\frac{1}{25}$ of an inch in diameter. The cathedral of Berlin has a cubical contents of about 17,300 meters, and it is heated by means of eight of these stoves, each of which has 22 of these brass gratings, measuring $11\frac{1}{2}$ in. in length by $1\frac{1}{2}$ in. in width, making in all about half an inch square of grating for each cubic meter to be warmed. The consumption of gas in raising the air within the edifice to the required temperature—an operation which takes three hours—is 83,400 liters, or 4.82 liters per cubic meter; to maintain the same heat afterwards requires only $\frac{7}{10}$ of a liter of gas per cubic meter.

The parish church of Berlin, whose cubic contents is 13,800 meters, is heated by four stoves, each having 15 brass gratings, each rather more than 12 in. long by $1\frac{1}{2}$ in. wide, or little more than $\frac{1}{5}$ of an inch of grating per cubic meter to be warmed. The annual consumption of gas in the cathedral above mentioned is 2,210 cubic meters, costing £20; this consumption is equal to 552 meters per stove, and 300 liters per $\frac{2}{5}$ of an inch square of grating. The consumption in Parisian churches warmed by gas is found to agree very closely with that of the cathedral of Berlin, but other cases give different results:

The church of St. Philippe at Berlin has a contents of 2,780 meters, and is heated by two stoves 1m. 40 high, 1 m. 10 long, and 65 centimeters in width, each having seven brass gratings 16 in. by 2 in., equal to $\frac{2}{5}$ of an inch square per cubic meter of the contents of the church. The annual consumption in this church is 1,485 cubic meters, or at the rate of 410 liters of gas per cubic meter of contents. But this church is only warmed three times a week.

The church of Saint Catherine at Hamburgh is heated by eight gas stoves, each having 32 brass gratings, 12 in. long by rather more than $1\frac{1}{2}$ in. wide; the cubic contents of the edifice is 33,900 meters. The heating takes three hours and a half, and consumes 220 meters of gas, costing about 27s. 6d., so that three liters of gas are required in this church per cubic meter of capacity; the temperature is kept up subsequently by the consumption of $\frac{3}{4}$ of a liter per cubic meter and per hour.

In the churches of St. Mary and Nicholas in Berlin, and in Paris also, a kind of large rose burner has been substituted for the brass grating; these are known in France as mushroom burners (*champignons*). The result with these burners in the first of the above named churches is as follows: The cubical contents of the building is 15,450 meters, and the consumption of gas in four hours is 150 cubic meters, costing about 35s., and as it is heated by ten stoves, each having three of these rose burners, the consumption per hour is $1\frac{1}{2}$ cubic meters of gas per burner, and nearly $2\frac{1}{2}$ meters for each meter of the contents of the church. In this case only we have the effect as shown by the thermometer, which is to raise the temperature of the church from one degree below zero to five degrees above, or from below thirty degrees to forty degrees Fah.

In heating churches and large buildings the economy of gas exhibits itself quite differently as compared with its application to cooking; in the former case, the more continuous the operation the less the relative cost, whereas in the latter the more frequent the interruptions the greater the economy. The objection to gas on account of its vitiation of the atmosphere of a building is one which neither the wire grating nor the mushroom burner has yet obviated.

DETERMINING THE POWER OF ENGINES.

By J. Deby, C. E.

From the "American Artisan."

Many rules are furnished in all treatises on the steam-engine for determining the horse-power, nominal or indicated, but none of them presents that scientific accuracy which alone gives real value to the results of experiments. The steam-engine (including its boiler, which is an intrinsic portion of itself) is nothing but a converter of heat into mechanical work; and consequently, in a general way, that engine which will approach the nearest to producing a maximum effect from a given quantity of fuel must be considered the best.

We know that a certain amount of any kind of fuel can only convert a certain determined quantity of water into steam of a given pressure, and we further know that this steam ought, theoretically, to do a certain amount of work. Starting from this basis, we can solve the problem without any great difficulty.

The first thing we have to do is to find out the exact composition of the fuel used. This is the duty of the analytical chemist, who tells us how much carbon, hydrogen, oxygen, ashes, etc., are contained in it. The carbon and hydrogen are alone the producers of heat, and all the other substances are absorbers of heat, and worse than valueless. Knowing the composition by weight of one pound of the fuel, if we multiply the amount of carbon contained in it by 8,000, and add to this product the amount of hydrogen multiplied by 36,000 (the units of heat evolved respectively during the combustion of one pound of carbon and of hydrogen), and then subtract therefrom the quantity of oxygen in the fuel, multiplied by 3,000, we obtain very approximately the total number of units of heat given out during the combustion of one pound of the fuel.*

If we divide this total number of units of heat given out by one pound of the fuel by the total number of units of heat contained in one pound of steam of the given tension (for which see tables or formula in the books), we obtain the number of pounds of water which might be converted into steam by one pound of such fuel in a *theoretically perfect* boiler. By carefully comparing the weight of water really evaporated in practice with the amount of fuel consumed for the purpose, we have thus an easy method furnished us for determining the efficiency of the boiler, fire-box, dampers, flues, etc.†

When we know by direct measurement how many pounds of water have practically been evaporated in our boiler by the combustion of one pound of fuel, if we multiply this quantity by the total number of units of heat contained in one pound of steam of the given tension, we find the total amount of units of heat which have been transmitted to the engine for the purpose of producing useful work. Multiplying this number by 2,000, the mechanical equivalent of a unit of heat, we obtain the number of foot-pounds of mechanical work which this amount of steam ought to produce if the engine were *theoretically perfect.*

Noting the number of foot-pounds thus developed in the space of one minute, and dividing this quantity by 33,000, we obtain the theoretical horse-power which would be derived from a *theoretically perfect* engine. By comparing the horse-power of an engine, as exhibited by the indicator, with the theoretical figure obtained by the method we have just exhibited, it becomes very easy to compute how near to, or rather how far from, perfection any particular steam-engine may prove to be. In the absence of an indicator, the "actual" horse-power may be determined by the ordinary formula for "indicated" horse-power, when the strokes per minute, length of stroke, and area of piston are known.

Let us give an example:

Supposing one pound of the fuel consumed to be formed of .92 of carbon, .63 of hydrogen, and .03 of oxygen, its calorific power would be $(.92 \times 8{,}000) + (.03 \times 36{,}000) - (.03 \times 3{,}000) = 8{,}350$ centig. units. If the engine is working steam of four atmospheres, or 59 lbs. to the square inch, each pound of steam will require for its production 651.8 units of heat, minus the temperature of the feed-water, which we will suppose in our case to be 51.8° centigrade, leaving 600 centigrade units of heat to be obtained from the fuel.

Dividing 8,350 by 600, we have 13.91 as the number of pounds of water which one pound of such a fuel could evaporate, *as a maximum*, into steam of four atmospheres. Now, if in our practical experiment one pound of fuel has only evaporated 10 lbs. of water, we see that a loss of 3.91 lbs. has taken place, equal to 39 per cent of the fuel used. *This first loss must have taken place through inefficiency in the boiler or its surroundings.* The 10 lbs. of steam of four atmospheres produced, contain $10 \times 651.8 = 6{,}518$ units of heat. Each of these units is the equivalent of 2,000 foot-pounds of mechanical work, and the 6,518 are equal to $6{,}518 \times 2{,}000 = 13{,}036{,}000$ of foot-pounds. If the 10 lbs. of water have been evaporated in 13 minutes, then $13{,}000{,}000 \div 13$, or 1,000,000 of foot-pounds will have been produced per minute, which, divided by 33,000, gives us 30 horse-power as the duty of a *theoretically perfect* engine. If, in our case, 20 horse-power only has been "indicated," then a 10 horse-power, or 33.4 per cent, would be shown to have been *lost in the engine alone* through friction, radiation, or from other causes.

In our example, 39 per cent of heat would have been lost in or around the boiler, and 33.4 per cent by the engine, showing a total loss of 72.4 per cent of the fuel burnt on the grates. Our experimental engine might

* The exact calorific values of bodies vary somewhat, according to the results of different experimenters. Those we give here are the determinations of Scheerer.

† Care must be taken, if the boiler primes, to make the necessary allowance for unconverted water suspended in the steam.

be said to be 72.4 per cent from perfection, and, in like manner, all kinds and sizes of steam-engines and their boilers may be rationally and simply classified and rated.

DRIED WOOD FOR BLAST-FURNACE FUEL.

By MARTIN MOSCHITZ, Royal Hungarian Counsellor of Mines.

Condensed and translated from "Oestr. Zeitschrift."

For a number of years it was intended to try, on a large scale, the use of dried wood in the place of charcoal in the blast-furnaces at Rhonitz, in Hungary. In 1862, all the necessary preparatory arrangements were completed, and the gradual replacement of 3, 5, 10, 15, etc., per cent of charcoal by dried wood then began. This had to be done very slowly and carefully, as the local circumstances did not allow of any interruption or disturbance of the regular working order. From this reason the increase of the percentage of wood had sometimes to be stopped entirely for long periods. However, these experiments were so successful that, from the beginning of the year 1866, the two blast-furnaces at Rhonitz have been running *exclusively* with wood, a result more favorable than was or could have been expected from the start.

In the period from 1862 to 1868, the furnace No. 1 was running during 331, the furnace No. 2 during 231 weeks, the fuel used being partly charcoal alone, partly charcoal and wood mixed, partly wood alone. The amount of materials melted were:

581,657 cwt. (Austrian) ankerites, poor spathic ores, and brown hematites.
371,832 cwt. granulated cinder from puddling and heating-furnaces.
296,917 cwt. calcarious and dolomitic fluxes.

1,250,406 cwt.

The fuel used amounted in that period to
4,981,974 c. ft. (Austrian) of soft charcoal (including 10 per cent loss).
4,709,899 massive c. ft. of pine wood.

The products obtained were
294,760 cwt. gray forge-pig.
71,700 cwt. castings.

366,460 cwt.

The percentage of iron in the mixture for forge-pig was 38.45, that in the mixture for foundry-pig 29.30. The charcoal weighed about 7 lbs. per cubic foot; some of it less. From 40 to 64 per cent of charcoal, by volume, have been obtained from the wood by charring, or 19.08 per cent by weight.

To be able to compare the amount of fuel used when the furnaces were run with wood, to the amount used when they were run with mixed fuel or with charcoal alone, it is necessary to convert, in the calculations, all the wood used into the corresponding weights of charcoal. It has thus been found that the amount of charcoal used for the production of 100 lbs. of pig-iron has been, on the average, as follows:

(*a*) In smelting with charcoal alone.. 195.09 lbs.
(*b*) In using 13.58 c. ft. of soft charcoal .... 95.06 lbs.
and 12.84 massive cubic ft. of wood, weighing 31 lbs. per c. ft., the corresponding weight of charcoal is $\frac{12.84 \times 31 \times 19.08}{100}$ ... 75.95 lbs.

171.01 lbs.

(*c*) In using wood alone (since 1866):
1. During the first 25 weeks were used 28.66 massive cubic feet of wood, the corresponding weight of charcoal is— $\frac{28.66 \times 31 \times 19.06}{100}$ ...... = 169.52 lbs.
2. All the rest of the time, up to this day, 27.02 massive cubic feet of wood the corresponding weight of charcoal....... = 159.82 lbs.

It is to be seen, from this statement, that by using wood instead of charcoal a saving of fuel is effected, amounting to (195.09 less 159.82) = 35.27 lbs. or 5.71 cubic ft. of charcoal, or 5.93 massive cubic ft. of wood, on 100 lbs. of iron produced. This is an actual saving of 18 per cent of fuel.

One pound of charcoal costs, at Rhonitz, .81 kreutzers (Austrian). [1 Austr. kreutzer is equal to about $\frac{1}{2}$ cent in gold. 1 florin = $48\frac{1}{2}$ cents gold = 100 kreutzers.]

One massive cubic foot of wood costs	3.9 kreutzers.
Transport, cutting and drying......	.8 "
Total cost of one massive cub. ft. of wood ready for use at the furnace,	4.7 "

From these data the saving in money, effected on 100 lbs. of pig, is calculated thus:

195.09 lbs of charcoal at .81 kreutzers = 1 florin...............	58.02 kreutzers.
27.02 massive cubic ft. of wood at 4.72 kreutzers = 1 florin......	27.53 "
Leaving per 100 lbs. of pig......	30.49 "

As the cost of 100 lbs. of pig amounts to about 2 florins and 30 kreutzers, the above saving corresponds to 13.2 per cent in money. This saving is, of course, the more considerable the higher the price of charcoal stands, when compared to that of wood. Fifty per cent of granulated puddling and heating cinders in the mixture are easily reduced and melted when dried wood is used as fuel.

The bast-furnaces in which the above results have been obtained are 42 ft. high, $3\frac{3}{4}$ ft. wide at the bottom, 12 to 13 ft. in the boshes, and 6 ft. at the top. They are shaped like the "blanofen" in which the Prussian spiegeleisen is made, the boshes running clear down to the bottom of the furnace in one steep incline. The mantel is carried by six cast-iron columns. The top is shut by a movable cover. Each furnace has four twyers into which the nozzles of the blast-pipes are fitted in tight. The nozzles are $2\frac{1}{6}$ in. in diameter. The blast has a pressure of $1\frac{1}{2}$ to 2 in. of mercury, and a temperature of 400° to 480° Fahr.

The gases are caught by a cylinder reaching 3 ft. into the mouth of the furnace. The circular space between the cylinder and the wall of the furnace is covered by a cast-iron plate with seven round openings equally distributed, through which the gases escape into seven vertical pipes all ending above in a horizontal circular pipe. Another pipe of sheet-iron, provided with a valve, communicates with the latter, and carries the gases to the places where they are wanted. The circular pipe has seven round openings above, situated in the prolongations of the seven vertical pipes mentioned. These openings, with short additional pipes cast on, are covered slightly by sheet-iron caps, which, like safety-valves, prevent the destructive effects of explosions. They also serve for the cleaning of the apparatus, and can be used to let the superfluous gases escape. The cylinder in the mouth of the furnace is necessary to prevent the atmospheric air, and the steam developed from the charged materials, from entering the gas-pipes. The sheet-iron main pipe carries the gases down 47 ft. to the general working level, and afterwards to a horizontal distance of 156 ft.

The cutting and the chopping of the wood is done by one and the same machine, which is of a peculiar construction. It consists of two steel blades working together like plate shears. The lower blade is fixed; the upper one moves up and down in a vertical frame. The blades are not straight, but are bent horizontally to a half circle, and their cutting edges are not even, but receding vertically in an elliptic line, so as to start the cut from both sides of the log held between the two blades. The logs, mostly about 12 in. thick, are cut in blocks from 3 to 6 in. high, which blocks are afterwards chopped in smaller pieces by the same machine. As all this is done by regular cutting, no saw-dust is produced. The cutting surfaces of the wood thus treated are not very even nor smooth, which circumstance facilitates the escape of the water in the following operation of drying. The above-described machine works day and night, cutting from 4,000 to 4,800 massive cubic feet of wood in 24 hours. The expenses for cutting by machine and drying of 100 massive cubic feet of wood, amount to about 30 kreutzers. Sawing and chopping by hand of the same quantity would alone cost about 95 kreutzers. In adding to this the expenses for drying, the sum would be too high to be paid for the preparation of wood for the blast-furnace. The wood, after being cut small, is filled directly into the charging wagons, holding about 20 cubic ft. The wagons are pushed into the drying-ovens without being unloaded, and when the wood has been dried, the wagons are conveyed to the top of the furnace. The drying-stove is a brick-building consisting of four parallel compartments. Each compartment is 48 ft. long, $4\frac{1}{2}$ ft. wide, and 5 ft. high, and has a door at each end, the one of which is the charging-door where the wagons filled with wood are pushed into the stove; the other door at the opposite end is the discharging-door, where the wagons are taken out one by one after the wood has been dried. A railroad with an incline of 3 to 100 passes through each compartment, so that the wagons, when pushed through the charging-door, roll of themselves towards the discharging-door. The stove is heated by the waste gases from the blast-furnace. It is, however, provided with a step-grate, on which a small fire is kept burning to re-light the gases when they have been extinguished during the charging of the blast-furnace.

The flame passes from the fire-hearth, near the discharging-doors, into four brick flues running below the floors of the four drying compartments, throughout their whole length; after this the gases pass through the hollow side walls of the compartments back to the vicinity of the discharging-door, where they find an outlet into the interior of the compartments, and thus come in direct contact with the wood. They finally pass, together with the steam that evaporates from the wood, through a flue near the charging-door, and escape into the stack.

It is to be seen that with this arrangement the wagons containing the wood pass gradually from the cooler into the hotter parts of the compartments. Each compartment holds 12 wagons, each wagon 20 cubic ft. of wood, the whole stove 48 wagons with a total volume of wood of 960 cubic ft.

At Rhonitz there are only 48 wagons in use, all told, and as a part of them are always on the way to and from the blast-furnaces, not more than 30 wagons are generally in the stove at one time. Both blast-furnaces require about 18 wagons of wood per hour or 60 minutes. Consequently the average time used for drying is about $\frac{30 \times 60}{18} = 100$ minutes, or one hour and 40 minutes.

Most of the wood used has been cut a year beforehand, and is therefore pretty well dried out in the air before being brought into the stove. It loses in the stove about eight per cent of water.

The practical management of a blast-furnace, when run with wood, does not differ essentially from the ordinary charcoal practice. The gas-pipes have to be cleaned oftener and more carefully, because the products of distillation from the wood settle partly in these pipes. The setting-in-blast of a furnace has, of course, always to be done with charcoal. However, after but a few days running, the fuel can be changed, and wood can be used exclusively, provided that the quantity of ore which the wood is able to carry under the existing circumstances has been ascertained by previous experiments. It is, however, very important when wood is used, to make the charges about 60 per cent larger than with charcoal, and to increase the pressure of the blast 10–20 per cent. With too small charges the considerable shrinkage of the wood is liable to produce irregularities in the descent of the ores in the furnaces. The higher pressure of the blast is necessary, because the carbonization of the wood being effected under more favorable circumstances and under a higher pressure in the blast-furnace than in heaps or piles, a considerably better and denser charcoal is produced, which requires a stronger blast to be burnt to full advantage.

The different and better quality of this charcoal has been practically ascertained at Rhonitz by a close examination of charcoal extracted from the lower parts of a blast-furnace running with wood.

It may be concluded, from what has been said above, that dried wood can be used to great advantage in blast-furnaces of at least 1,200 c. ft. interior capacity; when the ores do not pass through the furnace in less than 10 hours; when the wood is cut small, well dried and warm yet when charged; finally, when the top of the blast-furnace is closed, so as to avoid all the disagreements and disadvantages of an open and too hot furnace-mouth.

The use of wood in blast-furnaces has been tried as early as the end of the last century, and the trials have been repeated often in different places. They were, however, without success, from the following reasons. The furnaces were too small and open at the top. The preparation of the wood was done by hand, consequently very expensive, and the wood was not reduced to the proper size. The charges were taken too small, so that irregularities in the smelting ensued.

Explosions have been complained of in some places where the use of wood has been tried. But such have not been experienced at Rhonitz.

The advantages of the use of dried wood in blast-furnaces, in the place of charcoal, may be summed up as follows:

1st. Tops and small branches of trees, the carbonization of which cannot be effected in heaps or piles without a very considerable loss, may be used in the blast-furnace to great advantage.

2d. The whole process of carbonization is done in the blast-furnace in a more advantageous and less expensive manner, so that 18 per cent of charcoal is saved, and all the work that would have had to be expended on its preparation, beginning with the cutting of the trees.

3d. The furnace works well and with great regularity, and preserves a very clean hearth.

4th. Ores or other materials, which melt easily but are difficult to reduce, can be worked more advantageously with wood than with charcoal, as it is shown by the great amount of puddling-slag that has been smelted at Rhonitz, partly mixed with ores, partly alone. The greater density of the charcoal made in the blast-furnace seems to favor the reduction of these matters.

On the other hand the following disadvantages have to be taken into consideration:

1st. The expenses for cutting and drying of the wood are considerable, though with the machinery used at Rhonitz they are not as high as those for charring.

2d. The cost of transport is greater, because the heavier wood has to be conveyed to the furnaces instead of the lighter charcoal. This disadvantage is but small when the wood can be obtained pretty near the furnaces, and it increases with the greater distance from which the wood has to be fetched.

3d. As above-mentioned, it is necessary to clean the gas-pipes oftener. This disadvantage can, however, be entirely removed by erecting an apparatus for cleaning the gases from all the easily condensing substances. By this operation tar would be obtained, the value of which would pay for the expenses.

In general it may be said, and it has been proved by long practice at Rhonitz, that the disadvantages connected with the use of wood in blast-furnaces are by far out-weighed by the great savings effected by it when properly managed, and it is to be expected that the use of wood will enable many charcoal furnaces to withstand the increasing competition of the coke and anthracite furnaces. S.

RAILWAY DISASTERS.

WHAT KINDS OF DISASTERS CAN BE EASILY PREVENTED BY LEGISLATION.

From the "New York Times."

The awful frequency of railway disasters has at last set people to thinking whether some practicable means cannot be devised to prevent or lessen the horrors that attend them; and many theories of railway safety have been set forth in the newspapers by unprofessional experts, to the utter bewilderment of the public. But we have yet to learn that a single step has been taken by railway managers or by the Government to abate certain unquestioned and notorious causes of disaster which we shall enumerate —causes as well defined at Angola, Carr's Rock and Pine Tree, as at Mast Hope.

The misplacement of switches, for instance, even by men considered careful, often occurs, but the English system of signals would warn both engineman and fireman of the fact in *ample time to stop.* Hundreds of lives might have been saved by thus widening the range of notice and responsibility—it is almost impossible that three men will blunder in such a matter at the same instant—and yet not one in five hundred switches, passed by express trains at the top of their speed, is so guarded. We have, on a previous occasion, shown that not less than five men, practically asleep at Mast Hope that fearful night, might have saved the train if the appointments and regulations of the road had been adequate.

The preservation of trains from wreck, by safety brakes instantly applied to all the wheels, must have been a matter of experience with many of our readers; it has been so not less than three times with the writer, on one of the roads leading out of this city. But the use of such brakes is hardly increasing, and is not general.

An American train being connected merely by slack couplings, each car is free to sway laterally and vertically, even to the extent of jumping off the line, without restraint from the adjoining cars. The late Pine Tree disaster was, in the opinion of experts, especially of English engineers, who have commented severely upon it, greatly aggravated by this cause, and it is certain that many slight mishaps have grown into awful catastrophes for the want of the simple English appliances by which a train becomes an articulated whole, instead of a series of disjointed and independent pieces, each surging about without any restraint. On one of the few American lines where this system has been partially applied, it has been substantially neutralized by *adding the old links*, which are, of course, always used to save trouble.

Experts generally are of the opinion that a narrow-gauge car cannot run with the highest safety through wide-gauge frogs and guard-rails—in fact, that the late fearful Angola slaughter is a case in point—yet the inch and a half difference of gauge remains, and the number of cars suited to the one, and consequently unsuited to the other, but run over both, is constantly increasing.

The breaking of rails does not often occur when reasonable care is taken as to their quality and laying. Yet it is the opinion of the many engineers whom we have consulted, that a reasonable measure of safety cannot be secured without continuous longitudinal sleepers, or some mechanical equivalent thereof, which shall hold the broken pieces of rail in place long enough to pass a train in safety. But there is nothing of the kind in use.

Again, if there is anything clearly and positively settled in railway practice, it is that ricketty "permanent way"—broken chairs, rotten sleepers, loose spikes and rails, with parts of the head split off—are utterly and frightfully unsafe. But we will undertake to show any competent Government committee just this kind of track *by the hundred miles*—track that any commission of experts would refuse, upon examination, to ride over at high speed, and which is habitually left in this condition month after month. Yet when trains run off tracks of this general character, juries are utterly at a loss to account for it, and fall to speculating on the occult molecular differences in irons, the moral character of employees, and everything but what is obvious and pertinent.

There are in New England hundreds of old wooden bridges, designed when the stress put upon materials was much nearer the limit of strength than is now deemed safe—bridges that have deteriorated in the alternate rain and shine of twenty years, and which, being built for fifteen or twenty ton engines, are to-day straining under those that weigh 25 and 30 tons—bridges in which, according to engineers and bridge-builders, whom we have consulted, the iron rods are strained, when two engines happen to meet, up to 50,000 lbs. per in., when 10,000 lbs. is considered a safe working load. Now and then a wooden bridge falls under a train, and it is a dreadful but inevitable conclusion that hundreds of lives are yet to be sacrificed in this manner.

The most unnecessary, and at the same time the most frightful risk of railway traveling is yet to be mentioned—it is the risk of mangling and roasting by the splinters of the wooden car, that comprehensive and labor-saving engine of torture, for which, had the Adversary hatched it in their day, the Spanish Inquisitors would have thrown aside all their limited and clumsy contrivances. Upon violently striking any rigid object, the wooden passenger car is as certain to go off as a bombshell, with this advantage over the bombshell, that it has a percussion fuse at every angle, and completely surrounds the objects it is to destroy. Seriously, the wooden car is *certain to break up* in case of collision or derailment at high speed, and then the burning of the passengers is probable—their mangling is inevitable. Every few months, men, women, and little tender children are tortured to death, and this awful fate is certainly reserved for some of us. But not a single step has been taken by railway managers to abate this evil, though the remedy is practicable, and even economical in the long run. Iron cars neither splinter nor burn, and will out-wear wood again and again—yet we do not know that a single iron passenger car is contemplated.

We have thus specified a few of the most notorious and unquestioned causes of railway disaster—causes which do not involve the so-called hidden and unsearchable nature and changes of materials, nor any mere theories of construction, nor the vigilance and responsibility of employees. The remedies for all these universal, unfailing and ever-menacing evils are precedented and practical; some of them are almost ridiculously inexpensive; some of them would save their cost every year in lessened wear and tear, and all of them are feasible, simple and unembarrassed subjects for legislation. How many more murders will our law-makers ignore?

STEAM BOILER INSURANCE IN AMERICA—THE HARTFORD STEAM BOILER INSPECTION AND INSURANCE CO.—However unfortunate we in England may be in the matter of steam boiler explosions, no one can fail to have observed that our friends in the United States are still more so. The annual loss of life and property there, from this cause, must appear very large, even to the casual observer, whilst to those whose attention is frequently drawn to the subject, the results are really startling. It will be sufficient for the present purpose to allude to the record for the past two years, as it found its way into the papers. Such a record is, of course, a very incomplete summary of the number of lives lost, and the amount of property destroyed by boiler explosions in the time specified. Many explosions of a more or less serious nature are never reported by any newspaper, or, if reported, fail to meet the eyes of those interested in preserving an account of them. Incomplete, however, as it is, when we note the fact that, during two years, upwards of 800 lives have been lost in America by boiler explosions, and an immense amount of valuable property destroyed, ranging—in the various instances where any estimate was given—from $500 to $50,000, it demonstrates very conclusively the need of such a system of boiler insurance and inspection in that country as we have in our own. This necessity has been recognized—somewhat tardily, perhaps—by the Americans, who took a leaf out of our book, and in 1866 started "The Hartford (Conn.) Steam Boiler Inspection and Insurance Co.," about which association we have to say a few words. We are induced to do this from the fact that our journal finds favor in many parts of the States, where our persistent advocacy of boiler inspection is well known, and where the advantages of the system are admitted. If, then, the correctness of the principle be allowed, and if we point out to those who may not be aware of it, that American steam users have the same opportunities of making themselves safe as we in England have, there remains no excuse if they do not avail themselves of the means offered.

The Hartford Association is the pioneer company of the United States, and from particulars recently forwarded by a correspondent, we find that during the two years and a half it has been in operation, it has extended its business by a system of well appointed agencies over a great part of the country. Many of the largest manufacturers hold its policies, and its rapidly increasing business attests the value of its work. Its business is confined to no particular form of boiler, nor to any special class of manufacturers. It embraces ironworks, mines, cotton and woolen mills, saw mills, locomotives, steam-boats and steam-tugs, and, in short, all establishments where steam-power is used. All boilers under its care are carefully inspected, internally and externally, by competent practical men four times a year. Steam gauges are tested, safety valves properly adjusted and weighted, boiler connections carefully examined, and information given relative to setting and management. The end and aim of all this, be it remembered, is economy in the use of fuel, and safety to life and property. As a matter of course, the work of the company has brought to light many and dangerous defects; and there can be little or no doubt that disastrous explosions have been prevented. We know that where boilers are left unexamined for months and years together, incrustation, internal and external corrosion, burned plates and blisters, shorten their working age, and render them positively dangerous. The usual mode of inspection, applying the hydraulic test, takes no cognizance of these defects, and does but little towards insuring safety. The policy of insurance which the company issues, covers damage to boilers, buildings, stock and machinery, arising from explosions, and is a guarantee that the inspection has been thoroughly effected. It stands to reason that self-interest would cause the work to be properly done, inasmuch as the party making it has a pecuniary interest in its issue.

The company imposes no arbitrary conditions; it is interested in no patented appliances, but on receipt of the proposal for insurance, together with the inspector's report, the boilers are classified and accepted at a proper rate per cent, unless they are found on inspection absolutely unsafe, in which case the applicant is furnished with a written statement of their condition. Information relative to the management of steam boilers, monthly reports of the inspectors of the company, a list of explosions, so far as they can be obtained, for each month, and other valuable information, is disseminated amongst the policy-holders by means of a monthly paper called "The Locomotive." From what we have advanced, it will be seen that the Hartford Association is conducted upon equitable principles. The present remarks are penned with the view of promoting the interests of those steam users who are indifferent to themselves, and of increasing public safety. We, therefore, trust that they may lead those who may read them, and who have hitherto held back, either from ignorance or obstinacy, to avail themselves of the manifest advantages of inspection and insurance. It is an old and oft-reiterated opinion of ours, that it is due to the State that every man should adopt every precaution in his power to protect the life and property of his fellow subjects. A persistent disregard of this principle is a flagrant violation of the moral law, which the State will not always permit with impunity to the offender. —*Mechanics' Magazine.*

The Corliss Engines at Woolwich Arsenal, are using from 3.3 lbs. to 3.7 lbs. of coal, per hour per horse power, as shown by the daily engine reports.

BETON BUILDING.

From "The Canadian Builder."

Of all the compositions which in late days have been introduced as substitutes for brick and stone-work, there is not one that presents more attractions as a material than beton. But the use of it is limited to those localities where water lime can be had at a reasonable price. For, although that admirable cement is about the only one of its component parts that is expensive, yet the proportion used makes the beton more costly than could be wished, notwithstanding its many merits as a building material. There need not be any stone or stone chips used in the making of beton. All that is required to make a quick setting and very durable material is, sand, three part; water lime, one part; broken brick, six parts. The water-lime and sand should be well mixed together, dry. Then have as much water thrown over as will make a moderately stiff mass, when it is to be instantly transferred to the moulds, which are already in their place on the walls, and the center to be packed with the broken brick, which being very porous, will receive the moist cement readily on its broken faces, and help to set the whole. The mode of constructing the courses is by means of moulds easily adjusted and taken apart. They are to be calculated so as to enclose a block of beton of the required thickness of the wall, and half again that thickness in length. There height may be ten inches. Thus, if the wall be twelve inches thick, the block will be the same, and also eighteen in. long by ten in. high.

We will proceed to describe the operation of building as carried out in the construction of a beton house at Black Rock, near Buffalo, some years ago. The lines being laid out, the basement was excavated to the depth of six feet, and the trenches for the foundation walls dug out one foot and a half below the bottom of the basement. These trenches were two ft. and a half wide, that is, three in. each side wider than the basement wall above them. The basement was therefore dug three in. wider than the plan all around, and this was done to leave room for the placing of the moulding boxes with their rods. The bottom of the trenches was made level, and these were filled with concrete composed of six parts gravel, four parts sand, one and a half parts quicklime, with sufficient water. When this mass was well mixed and turned over three or four times, it was thrown into the trenches in layers or courses of four in. in depth. Each course was spread over the whole of the foundation trenches, until they were all, including the foundation of cross-walls, filled. When the surface of the basement or cellar bottom was reached, then the whole area was gone over with a coat of gravel, and over this was poured a creamy mixture of water lime and sharp river sand, in equal proportion, until the whole was flush. This was done on Saturday, and on the following Monday the floor was hard enough to walk upon. The basement walls were now commenced in the manner here described. The lines of the walls as shown on the plan were carefully laid out, and angle-moulds placed at each corner, with straight moulds set at equal distances all along.

One corner mould and three or four straight moulds are sufficient to work with; but the greater the number of moulds the more expeditiously the operation of building goes on. When all was ready, the corner moulds were filled first, and then the other moulds regularly in turn. When all were filled, the moulds were taken apart and set up at other points along the walls; but sufficient time was given for the beton to become hard enough to admit of being uncovered. The walls being thus gone round the next operation was to enclose the spaces between the beton blocks, and this was done by using the sides of the moulds, without the ends, and holding them in place by the following means: Two pair of pieces of scantling two by three in. each, and two ft. long, were set upright at the ends of the side boards, and bearing them against the beton blocks. At the middle of their length they were held by the rods and screws used in the moulds, and their upper ends being apart by sticks of the necessary length, the boards were thus clutched and kept in place. These inclosed places were now up flush in the same manner as the moulds, and by packing and tamping, the connections were rendered so complete as to make the whole a uniform mass. When each course was in this manner completed, the moulds were laid for a new one, taking care to break joint though no joint was visible, yet this precaution was taken to avoid any continuous joint or point of imperfect connection. Where doors or windows occurred, the moulds were placed correspondingly, one on each side of such opening; for it may be observed that there is no necessity for the fixing in of the frames until the work is all sufficiently set. However, it is necessary to insert these moulds at doors and windows, at the ends, which will form the jambs of such pieces of scantling called stops, four in. thick, and sufficiently wide to permit the future, frame to rest five or six in. back from the outer face of the wall. Of course the frame can be set up and the jambs worked up to it, but it is more troublesome and will scarcely make as good a job. The window-sills and caps were provided for in like manner, and there was a splay left in the window jambs, by means of angular pieces being added to the above mentioned stops, which gave the required mould to the beton. When the level of the ceiling was attained, the flooring joists were all set up in their places, and temporary bridging of plank fixed between every every pair, so as to hold the beton which was thus continued up, making a compact bed for the joists, and effectually preventing the lodgement of vermin. The short boards or pieces here used may be removed when the work is set, as they will be wanted again on the next floor. In the building we describe they were left in, but it is not at all necessary.

The joists being all flushed up with the beton, the floor boards were nailed down and the beton again flushed up to the surface of the floor. The moulds were now placed for the walls of the principal story, which being six in. less than than those of the basement, the ends of the moulds were made in accordance with the new thickness, namely, twelve in., and the work went on as before, with the exception of the corners of the main walls which were rounded by means of blocks of the necessary shape being set in the angle. This rounding off of the wall on the outer corners gives a very neat appearance without adding to the cost. On the contrary, it economizes the material; for the thickness of these corners instead of being greater on the diagonal, is exactly the same as that of the straight walls throughout. In the manipulation of the beton for the walls of the superstructure, it was deemed advisable to pack the front of each mould with a finer coat of cement than that used at the heart, or even at the back, so as to give a uniform face to the outside. This face was carefully troweled into the bed made for it in the mould, by working back the coarser beton in which the broken brick was packed. In the top of the first tier of blocks forming the course, an angle mould was laid along and pressed into the fine beton forming the outside face. And on the bottom of the next tier of moulds, a corresponding angle mould was laid and the beton cast firmly around it. And thus every course was treated. The consequence was that the cincture left on the removal of these moulds produced an effect on the exterior remarkably like coursed masonry, the course lines being of the > shape, about two in. wide, and one and a half deep. Other sections of cincture can be moulded to suit other designs of building. After each course was uncovered, these sunken mouldings were finished smooth by working a whole mould of the > shape along them, backward and forward. Perpendicular moulds of like shape might have been made to mark out each block, and no doubt would have improved the appearance of the building. The sunken horizontal courses were carried all around the house and produced a good effect. The next floor was flushed up at the joists precisely in the same manner as the first or principal floor. The windows and doors all set in and worked up to. But this is not the better way. The sills and lintels were of oak, but the latter did not show on the outside. It would be much better to have stone sills and lintels. The partition walls were six in. thick, and were cast in unbroken courses, with the exception of openings for doors. The door cases were set in and worked up to. Blocks were nailed to the floors at the walls and partitions, to receive the base board of the apartments—and these blocks were covered up in the beton. In like manner there were blocks inserted for nailing finishing of windows and doors to, and for holding the horizontal slates from which to hang pictures. The roof was a gabled one, of a fourth pitch, but a Nansard would have been a great improvement. The walls were skin coated on the inside of the house, and the best rooms were hard-finished. Nothing can be easier for the plasterer to make a workmanlike job with; for his material is sure to adhere to it. There is little more to add, save that the chimney-flues were all cast round by means of stovepipes used as moulds and left in. This is not a good plan, as the stovepipe will corrode after a time, and it is very difficult if not impossible to remove it. It would be better to use a movable cylinder mould with a handle, and have the flue finished smooth in beton. The chimney shafts can be very ornamentally finished with terracotta caps.

To those who can procure water-lime at anything like a reasonable price, we would strongly recommend beton as a particularly applicable material. It is warm in winter, cool in summer, and at all times dry and healthful. In mixing common lime with it —of course for economy's sake alone—it will be well to bear in mind that, whilst quick lime swells in slaking about one-fourth, water-lime on the contrary shrinks about a fifth. By experiment on the limes to be used, exactness can be attained. By thus calculating, the two may be, so to speak, dove-tailed into each other.

INDUSTRIAL PARTNERSHIP.

A humane tendency towards the improvement of the condition of the working-classes evidently exists in all civilized countries. Many systems have been invented and tried, and many have failed. The old French communistic principles have been found totally impracticable. No means have succeeded in England as yet to universally prevent great and long-continued strikes so ruinous to both capitalists and workmen. The idea of Lassalle in Germany that the "help" has to come from the governments, was not able to rouse the latter from their impassibility, nor to inspire confidence in the greater number of the workmen. The second empire in France undertook to calm the laboring classes by an unprofitable occupation, at the expense of the whole people, in the embellishment of the capital. This great and beautiful but to a great extent fruitlesss work is not yet fully accomplished, and already we hear of seditious scenes that occur in the embellished capital. In this country the vain attempt has recently been made to regulate by law certain relations between capital and labor, relations which under a despotic goverment only, could be regulated otherwise than by the free will of both the concerned parties, by voluntary agreement between free men and free men, between laborers and capitalists, when they acknowledge each others rights and when they recognize and own that the interest of the one is the interest of the other. The eight hour law was totally ineffective, as might have been expected before hand. A real and great success in improving the condition of the working-classes was, however, obtained in Germany by Schultze-Delitzsch, whom A. S. Hewitt in his report of the Paris Exposition of 1867, calls therefor "the greatest benefactor of the human race in our days." This system is based on the principle of "self-help" through associations of consumption, of work, of money, through education and enlightenment, inevitably followed by moderation and good sense. In other places may be read the accounts and statistics of the great number of societies for supply of materials, for co-operation for mutual credit, for acquiring a higher than the ordinary school-education, as they have been established among workmen all over Germany, especially under the influence and practical guidance of Schultze-Delitzsch. Great as this success may be, yet the question is considered in Europe where its solution is more urgent than here, of such a high and immediate importance, that new schemes yet continue to turn up and to be discussed. There is one amongst these which merits special attention because it benefits both capitalists and workmen, and because, to judge from the practical successes already obtained, it seems to be the proper way to perfectly unite in single instances the interests of both. It has been called "Industrial Partnership," and consists in giving to the workmen an actual interest in the business for which they work.

In a meeting of the engineers of the Lénne-district, held at Lethmate (Prussia) on the 12th of July, 1868, Mr. C. Kugel delivered a lecture on this subject from which we extract the following interesting remarks.

"In England where this system has originated, the motives which led to the first trial, were dictated to the capitalists not by humaneness, but by mere egotism. The relations existing between employers and employees in many districts were then such that the two parties stood opposite each other like two hostile armies, ready at any time to begin an open war. To alter this condition injurious to both parties, it was thought of granting the workmen a share of the profits, thus to inspire them with more interest for their work, thereby to increase and improve the production and to attain to the greatest economy in the manufacture. It was expected that carelessness in working would thus be checked or at least greatly diminished, because the workmen would mutually control themselves.

"The first trial with Industrial Partnership was made at the large carpet factories of Messrs. John and Francis Crossley at Halifax (Yorkshire). These works embrace an area of $18\frac{1}{2}$ acres of land and a capital of £1,500,000. They employ 4,500 persons.

Messrs. Crossley divided the whole of their business-capital into shares, the fifth part of which they offered and sold to their employees at £15 per share. By this operation they obtained not only perfectly satisfactory relations with the workmen, but a great material gain. Within the first three years after the introduction of this system, the yearly dividends amounted to 15 per cent, and a reserve capital of £11,284 was acmulated besides. In the greatest financial crisis the value of the shares of this company did not sink below £17. A success more brilliant yet was obtained through Industrial Partnership at the coal mines of Messrs. Briggs at Whitewood and Methley junction, near Normantown. Continual dissensions between the proprietors and the men existed at these mines from 1853 up to 1863. In the years 1858 and 1863, regular strikes took place. The proprietors in consequence concluded to sell one-third of their mining-property to their workmen, and to other persons in shares of £15, of which £10 had to be paid in at once. The workmen at first showed some diffidence. But very soon the demand for shares increased to such an extent from all sides that Messrs. Briggs kept in their own hand only 6,450 of the existing 10,000 shares. They sold 1,068 to their customers, 1,847 to the general public, 114 to their agents and 264 to their workmen; 230 more were reserved for further purchases from the latter. The office-employees took 86 shares, and the other 178 were sold to 83 miners and 61 laborers. As the works occupy in all 785 miners and 204 labores, one share is, in the average, in the hand of one amongst nine miners, and one share is in the hand of one amongst three laborers. No one, Messrs. Briggs of course excepted, can hold more than 6 shares according to the agreement. These mines which in former years in consequence of strikes and bad work, did not pay any interest whatever, have been able to distribute from £15,000 to £18,000 of dividends in the last three years and have besides accumulated a considerable reserve.

" The North-western Manufacturing Company in Chicago introduced the Industrial Partnership in the following manner. The weekly earnings of every workman were calculated from the average wages for a daily work of 10 hours. It was agreed that the whole body of workmen should receive in addition to their regular wages, the one half of the net profits exceeding 10 per cent of the capital. The distribution of these profits is effected in proportion of the wages earned by every single man, as found by the just mentioned calculation. The shareholders are to receive 10 per cent of the capital and the other half of the excess. According to communications received from Chicago, $50,000 of profits were obtained from one year's business with a capital of $250,000. The share of profits paid to the 140 workmen of the factory were therefore $12,500. Mr. Borchert, jun. in Berlin (Prussia) was the first German house who made a trial with the system of Industrial Partnership. Mr. Borchert estimated the value of his establishment at 300,000 thalers and divided this sum in 12,000 shares of 25 thalers each. He allows one-tenth of them, or 1,200 shares, to be bought and owned by his workmen and employees. The share-holders constitute a company for themselves. They elect three of their members as directors. The latter have the right to inspect the books, and they receive every month full information on the condition of the business from the proprietor who is also the general manager of the factory. As soon as three-tenths of the shares will be sold, the directors elected by the shareholders, will have a direct influence on the business transactions. One half of the net profits (probably after deducting a certain interest on the capital) is divided among the workmen in proportion to the wages received. These, however, who are steadily employed and paid by the week receive a greater part in proportion than those who are paid by the piece. The other half of the net profits is divided amongst the shareholders."

After having made these communications, Mr. Kugel in his lecture further alluded to the difficulties which in many places may oppose themselves to the introduction of Industrial Partnership. He thought however that, to judge from the brilliant success obtained with it in some establishments, it deserves to be warmly recommended. The introduction has of course to be done cautiously and with special regard to local circumstances. He finally expressed the opinion that the institution of Industrial Partnership will prove a better and safer step toward the solution of the so-called "social question," or the question of the improvement of the social position of the working-classes, than even the institution of productive associations.

We cannot conclude this article without directing the attention of our readers to a remarkable feature which some of the above mentioned examples of partnership have in common. The proprietors do not sell a certain number of shares to their workmen without selling at once a much larger number to outsiders. This appears to be an important point which prevents direct disputes between the shareholding workmen and the proprietors about the profits and the dividends. This remark does not of course, apply to those cases in which the proprietors, without selling any shares, distribute amongst their workmen a certain part of their profits as a free donation. S.

MAKING FOUNDATIONS IN MARSHES.—A new process of making foundations for bridges in marshy soils has been recently used on a branch line of the Charentes Railways Company in France. This line crosses a peat valley to the junction of two small rivers; the thickness of peat was so great that any attempt to reach the solid ground would have been very expensive. In order to obtain cheaply a good support for the bridge, two large masses of ballast accurately rammed were made on each bank of the river, and a third one on the peninsula between the two. The slopes of these heaps were pitched with dry stones, for preventing the sand from being washed away by the rain or by the floods in the rivers. Over the ballast a timber platform is laid; this platform carries the girders of the bridge, which has two spans of about 60 ft. each. When some sinking down takes place, the girders are easily kept to the proper level by packing the ballast under the timber platform; this packing is made by the platelayers with their ordinary tools. This simple and cheap process has succeeded quite well.

The same difficulty was overcome by a different plan on an ordinary road near Algiers. This road crosses a peaty plain nearly one mile broad; the floods and elasticity of the ground prevented the formation of an embankment. The road was to be carried over a viaduct across the valley, but the foundations of this viaduct presented serious difficulties, the thickness of peat or of compressible ground being nearly 80 ft. It was quite possible to reach the solid ground with cast iron tubes sunk with compressed air, or with any other system, but neither the implements nor the suitable workmen were available in the colony, and it was a great expense to bring them, and especially the workmen, from France. The use of timber piling was of course out of question, as timber is very expensive in Algiers and quickly becomes rotten; but there was a set of boring implements with the men used to work it. The engineers began boring holes 10 in. diameter down to the solid ground. These holes lined with thin plate iron pipes were afterwards filled with concrete up to the level of the ground. Each of these concrete columns bear a cast iron column; these columns are properly braced together and support the girders of the viaduct which is divided into spans of about 20 ft. and is 20 ft. high over the ground. This system has succeeded very well, and is to be extended to another larger valley.—*Cor. The Engineer.*

STEAM AND POWER HAMMERS.

From a paper before the Civil and Mechanical Engineers' Society, by Mr. FREDERICK H. ROBERTS, C. E.

The author referred in detail to some of the earlier machines, such as the helve or tilt hammers used for shingling, forging blooms and shafting, tilting steel, etc., but as this class of machine depended, to a great extent, for raising the hammer and its connections, either through the direct medium of cams, eccentric, or similar arrangements, it followed that the power required to work them was extremely large, and the parts of the machine itself very heavy and cumbersome to withstand the consequent strains. It was also found that the larger the mass of metal to be worked, the lighter the blow given, and, conversely, the smaller the mass, the heavier the blow; it was, therefore, ill adapted for heavy forgings. The invention of the steam hammer solved the difficulty which was found to exist, and to it, to a considerable extent, is due the perfection obtained in all classes of machines where ponderous forgings are found to be absolutely necessary.

The first idea with reference to the steam hammer the author traced as belonging to that great engineer, James Watt, who obtained a patent, in 1784, for heavy hammers or stampers, for forging iron, copper, or other metals without the intervention of rotative motion, by fixing the hammer head either directly to the piston or piston-rod of the engine. Another patent followed this in 1806, by a Mr. Deverell. He proposed to admit steam underneath the piston of an engine by means of a valve, and during its up-stroke the air at the top of the piston was compressed by the pressure of steam beneath, which was released at the proper moment. The compressed air on the top of the piston, in addition to the gravity of the hammer head, was to give the blow. But neither of these ideas were put into practice at that period, and it was not until 1837 that any practical design was put forward for a steam hammer, and then by Mr. Nasmyth, of Patricroft, who urged its superiority for working metal over all other machines, but was unable to procure its adoption until about 1840, when he found that M. Schneider, of Creusot, profiting by his design, had constructed a machine on his plan. In 1842, he obtained a patent for his steam hammer, and from that time it became a recognized power, and a necessity in all works of importance. The facility which it afforded for executing all kinds of forging had the effect of greatly increasing the quantity of work to be done, and effecting a material saving both in time and labor.

The steam hammer, as originally constructed, required the valves being worked by hand, which left the machine in the power of the workman to give proper efficiency. The valves were also very difficult to work. This plan answered for the time for small machines, but where rapid motion was necessary, and for larger hammers, it was unsuitable. Several designs for self-acting motion, therefore, followed in quick succession. The author then referred to the different designs that had been introduced for this purpose. In the ordinary self-acting hammer, the man has to watch the metal under operation, and, as its form and position change, he must set his valve gear to suit as near as possible. The author considered that the motion, to be properly self-acting, should be independent of the workman as regards the adjusting of the gear to suit the varied thicknesses of the metal on the anvil; and, in order to obtain the full force of the blow, it should reverse simultaneously with, or immediately after the blow is given, and at whatever point in the stroke the blow takes place. He considered that was accomplished in Sturgeon's double-action hammer, where the blow itself was made use of as the agent to work the valve, and described the mechanism employed; also the various types of double-action steam hammer; likewise the numerous modifications and improvements effected. The author then spoke as to the specialities of the heaviest classes of steam hammers of modern date, including those of Mr. Ramsbottom's design; likewise those erected for M. Krupp, at Essen.

With reference to machines of a lighter class, the author described the various designs for power hammers, and referred to the patent pneumatic hammer, several of which he had erected, and which are specially adapted for general smithy work, or light forgings, planishing and beating out metal, etc. It is extremely simple in action, working by means of the alternate exhaustion and compression of air within two cylinders, in one of which is a piston, to which the hammer head is connected by means of the piston-rod. By opening a small valve, the vacuum formed within the cylinder is destroyed, and the blow weakened or stopped instantly, according to the amount of the valve opened. The machines are capable of working up to 500 blows per minute when required.

IRON-FOUNDING.

UNITING CAST-IRON BY "BURNING-ON."*

From the "Practical Mechanic's Journal."

Connecting lead with lead, by running a stream of very hot liquid lead, suitably confined, in contact with a surface of solid and cold lead, until the latter had got to its melting point, and then stopping the current, so that the two portions become united when both solid, has been known to plumbers for ages under the name of "burning together." In fact, by this method some of the earliest lead water pipes were made before "drawn pipe" was known.

This same method of "burning together" may be also employed by the iron-founder, and occasionally with great advantage. The writer, in the course of his early practice, had occasion to cast four of the very ponderous columnar cast-iron frames which, in the earlier days of steam navigation, were to be employed for the "side frames" of side-lever marine engines of the heaviest class. The frames in question consisted of coupled Roman-Doric columns of considerable diameter, cored out, with cross framing and entablatures, also all cored out, and with sundry projecting pieces like truncated horns etc., whereby the frames were to be united

* See also Van Nostrand's Mag., No. 8, page 705.

with other "thwartship" pieces, each frame weighing several tons and consuming a large amount of wages in moulding.

All four were cast sound and without a blemish, except that, upon the top box in which one of these was cast—all being cast in green sand—some one had unluckily dropped a bar or something heavy, or put a foot upon it, and produced "a crush," which rendered one of these horns utterly amorphous. The casting, otherwise perfect, was in that state absolutely useless, and was about to be broken up, when the writer resolved to try and save it by attempting to "burn-on" a new and perfect horn. The old and defective mass was carefully cut off, and removed down to absolutely sound metal. "Loam cakes," having the proper form for the horn, were taken from the pattern, the surface of the cut metal was well dusted over with powdered glass of borax, after that the mass of the "frame," in close propinquity with the defective place, had been heated red-hot in a coke fire built up around it. The fire was then raked away, the loam cakes secured in place, and several hundred weights of very hot liquid cast-iron were for some time kept flowing through the cavity of the loam cake hollow-mould. At length the flow was stopped, when the cut surface could be felt, with the point of an iron bar pushed through the running metal, to have become pasty and soft, and the iron was then permitted to set. When finally stripped and "gaits" etc. removed, the new horn was found to be perfectly united with the remainder of the casting, and when struck it gave the clear sonorous ring which proves complete metallic continuity.

The success, in fact, was perfect, and somewhat surprised both the writer, to whom so large an instance was new, and the marine engineer responsible for the supervision of the work, who would not pass the casting until he had assured himself of the safety of the horn by striking it heavily with a sledge-hammer. This method is capable of being applied not unfrequently with similar ends in view, and may often save the condemnation of a casting and effect a good deal of economy. It can almost always be made effective, if the methods be judicious, for attaching, as in the above case, a heavy piece to a heavy casting; but it is a far more delicate and difficult task to make succeed with smaller and more delicate work, and there are two generic cases in which it is useless to attempt it.

One of these is where the form or dimensions, or both, of the casting must remain *precisely* the same after the work as before; as, for example, if a piece be defective in the rim or in one of the arms of a large spur or head gear-wheel, there would be no great difficulty in replacing it soundly by casting together as described; but either the wheel would crack somewhere on the setting of the "burnt-in" metal, or during its cooling, or it would have lost its circular form and "truth" when all should be cold.

Again, if the mass of casting be very great, and it is but a whole or cavity, regular or not, that requires to be filled in with metal, which must be perfectly united with the remainder, this can scarcely be accomplished unless at an expense that renders the process worthless; for *the whole* huge mass must be brought to a strong red heat, with great expenditure of fuel and time and surface injury to it by oxidation, or the union will prove imperfect. Such has been the fate which has always attended attempts, thus to restore defectively cast cylinders for hydraulic presses. The writer, however, has little doubt but that a sort of small coke-fed furnace, with a strong blast, delivering from a small brick-lined mouth a jet of flame like that of a large blowpipe, might be so used as to heat even up to the melting point—and but very locally or partially—any mass of cast-iron, however huge, so as to admit of "burning on" to it. He once witnessed sufficient proof of this in the method taken to repair a defect which appeared in the neck of a very heavy cranked intermediate shaft for marine engines, at the Thames Iron Works, just before Mr. Mare ceased to direct them. The neck of the crank, about eighteen in. diam., was rough-turned, when a hole was found and cut into in the forging, close to the angle of the neck where joining with the arm or side of the cranked part. Nothing could be more awkward as to position, and the condemnation of the whole forging, and serious loss, seemed imminent. The foreman blacksmith determined upon one trial to save it. He got up just such a coke-fed giant blowpipe as has been described, and drove its flame right into the defect or cavity, having carefully "clayed up" the iron of the rest of the crank adjacent, to save it from oxidation.

In about five hours he had the interior of the cavity at a fine uniform and clear welding heat. A piece of wrought-iron, well-judged—as to form—to rather more than fill it, had been got ready, and at the right moment was brought, in a forge-fire, to a welding heat also; and the blowpipe blast being thrown off, the welding hot plug, preceded by a dust of sand and borax glass, was thrust against the cavity, and a single blow of a "tup," beforehand properly swung ready, sufficed to firmly weld it into place. The superfluity, when cold, was chipped off, and the turning of the neck completed, which the writer witnessed; and he can testify that it was not possible upon the clean cut surface then to discern where was the new iron, and where the surrounding old of the original forging. The work reflected much credit upon the skill of those who conducted it, and in that respect alone deserves to be recorded. The method of heating, however, is quite as applicable to cast as to wrought-iron.

The marine-engine framing above referred to was treated about 1833. In the "Annales des Mines" for 1860, M. Mengy gives a circumstantial account of the same method having been applied about the same date at the Tamaris Iron Works, Departement of Alais, to burning-on the broken-off necks of the iron rolls of the rolling mill, and with complete success. Dr. Percy ("Metallurgy," p. 745) states that he has seen a roll thus repaired at the Millwall Iron Works, and that the method has been in occasional use elsewhere.

Dr. Percy also gives an interesting account of the Chinese method of mending or stopping holes in their very thin cast-iron rice bowls or boilers, when broken through these brittle vessels, by means of a plug of pasty cast-iron adroitly applied by the native "tinker." He cleanses the edges of the hole, melts a sufficient large bit of cast-iron in a small crucible, in a little charcoal furnace, tilts the liquid iron out upon a folded damp cloth spread with ashes and held hollow in the hand, and at the moment before the cast-iron assumes the *pasty state* just before "setting," he thrusts it up to the outside of the hole and through it, and smoothes the overplus at the inside with another like cloth; so that he has thus made a sort of irregular rivet of the semi-liquid material. There is here, however, no metallic union. The case is precisely analogous to the manipulation by which the plumber makes a "wiped joint," applying the semi-liquid plumbers' solder, held in the hollow of his "tickenfelt," rapidly and adroitly to and around, the shaved and tallowed surface of the adjacent ends of the lead pipe to be united; and equally analogous to the way that holes in earthenware vessels are sometimes mended in this country, by a semi-liquid rivet of fusible metal quickly pushed through and smoothed over on both sides. It is not impossible but that more extended uses of this same method and of the analogous properties of cast-iron, though at its much higher temperature, might be found if looked after.

Where a mere cavernous defect exists in castings which injures appearance only, and which may be filled up level as sufficient remedy, cast-iron is very often dropped into the hole and the surface instantly scraped or cut off level by shoving an iron straight-edged scraper across the mouth of the now filled-up hole. This, however, is seldom a very neat method of repair, and some iron-founders adopt for the filling material an alloy which is almost identical in color with the dark surface of freshly-made castings, but is much more fusible than cast-iron.

This alloy is said to be best composed as follows:

Antimony	65	
Copper	16	
Lead	13	by weight.

Some prefer—

Antimony	69	
Copper	16	
Tin	2	
Lead	13	by weight.

The copper, tin and antimony are melted together first, and the lead then added.

Where, for such operations as are above referred to, defective or other parts of castings, more particularly of large size, require to be cut off, if there be suitable appliances at hand, they are much more easily removed at a cherry-red heat by means of a rapidly rotating circular saw, as in cutting off the ends of rolled iron rails, than by cutting away with machine tools or by hand, cold. Indeed, in many ways besides this, cast-iron is an extremely tractable material at a low or cherry-red heat. Thus, for example, at that temperature, castings which have been molded flat may, if need be, be curved by bending over a saddle of suitable form and to almost any extent.

Or curved pieces, buckled in the cooling, may be forced back flat, or the curvature of pieces, which have too much departed from that of the model, by contraction in cooling, may have their curvature corrected, etc.

The writer once cast a great number of very thin perforated flooring plates for a bridge, which were required to be curved into arch plates. They were cast quite flat, which, owing to peculiarities of form and perforation, was found the best plan to secure soundness, and then curved by bending over a saddle of baked fire-clay; for the saddle must not be of good conducting material, or the casting gets chilled and possibly broken.

Blackfriars New Bridge.—When one of average imagination, distant foreign travel, and general reading, sits down to write about the last important bridge that has been built in this country, he cannot avoid a dream-like glimpse at bridges everywhere; the natural bridges of South America, with earthquakes for their engineers, contractors, and workmen; the many thousands of primitive bridges in China, formed of huge slabs of stone, brought in many cases from immense distances by human labor; the numerous interesting bridges in France, Germany, Switzerland, and other parts of the continent of Europe, not to speak of the triumphs of this generation's engineers in overcoming almost all conceivable kinds of difficulty in bridge construction that could be presented by climate, materials, situation, or other circumstances in every quarter of the globe. * * *

Blackfriars bridge is altogether formed of wrought-iron so far as the main structure is concerned—the embellishments only being of cast metal. Preparatory to the actual commencement of this important undertaking, the erection of a temporary wooden substitute, as well as the demolition of the old bridge were necessary. The first piles for the requisite gantry—one-third of which is now removed—were driven in, June, 1864. As it is generally considered in the London district that the London clay must be reached to obtain a sure foundation for large buildings, this course was here followed, involving three or four months of incessant daily and nightly anxiety and labor—on account of the tides. For our part, however, we coincide with the opinion of some eminent practical engineers, that there is no absolute necessity for going down to this clay, and that consequently, in doing so, much needless expenditure of time and money is incurred. The bridge consists of five arches, namely, two of 155 ft. span each, two of 175 ft., and one of 185 ft. The height of rise in the center arch is 17 ft., and in the others 16 ft. and 12 ft. respectively. Instead of regularly-framed centring, piles were driven down to support the ribs where required, which doubtless saved the contractor much expense both in erection and demolition. The ribs were then wedged up to the soffit of the arch; these wedges or slacks are now removed, so that each arch rests on its own skew-backs, and the piles can be taken away at once. Mallet's patent buckled plates, which, as most of our readers know, are made of about $\frac{1}{4}$-in. plates of iron placed heated over a mould and stamped by hydraulic pressure into the shape of a groined arch, are bolted to the roadway bearers by $\frac{5}{8}$-in. rivets, and form an immensely strong platform. On this is put one inch thick of asphalte; over this again—an addition to and improvement on the usual practice—a layer of broken stones and asphalte, from 9 in. to 12 in. in thickness, is placed; and lastly, on top of all, is granite pitching as ordinarily laid on roads. The total length of the bridge is 1,272 ft.; its width, including the roadway of 45 ft. and two footpaths of 15 ft. each, is 75 ft. The gradient is 1 in 40. There are eight polished red granite columns, between which there are parapets 3 ft. 9 in. in height. Over each column there are recesses in which there are seats capable of resting ten or a dozen weary pedestrians. A handsome row of lamps will be placed along each pathway, a little back from the kerb—a plan not adopted on any other of the Thames bridges—and they will be so arranged as to facilitate the navigation after dark. The balustrades are Venetian-Gothic in design. They were beautifully cast by Messrs. Lloyd, Foster, and Co., at their works in Wednesbury, Staffordshire, and will form an elegant adornment to the broad York stone pavement. This, with the Thames Embankment, which will meet the bridge at the north abutment on the same level, will form a promenade, on which, no doubt, the ghost of Dr. Johnson will vary his "walk down Fleet-street," and which will prove a source of health and recreation to the pent-up denizens of the City. Viewed from the river, either in ascending or descending the stream, Blackfriars Bridge will present a fine appearance with, as will of course eventually be the case, characteristic groups of statuary to crown the abutment piers, capitals on the polished granite columns, representations of sea-birds and plants on the east, and of their fresh water prototypes on the west façades, finished by the sky line of the chaste parapet, relieved at intervals by the handsome lamps.

The cost of the erection and maintenance of Blackfriars Bridge will be defrayed from the funds of the Bridge House Estates, the revenue of which is some £40,000 per annum, and to which £21,000 will fall in, in a couple of years, from terminable annuities, on which money was advanced by Government for the building London Bridge.—*The Engineer.*

THE GREAT BRONZE FOUNDRIES OF FRANCE.

From "The Practical Mechanic's Journal."

The casting in bronze, as the chief amongst several metals or alloys by which the artist can endurably entrust the conceptions of his imagination to a remote futurity, mounts as an art to the very earliest yet known origins of our race. China, India, Babylon, Egypt, Greece, Rome, the middle ages of our Europe, the Renaissance, and our own day contribute their monuments or testimonies of this. And yet, in some senses, the art has never spread, or become a diffused or universal one; at this moment there is really but one great bronze-casting nation in the world—France.

England has not been absolutely without attempt to establish bronze-foundries of works of art; but while we have dozens of brass-foundries existing chiefly as integral parts of our great engineering establishments, in which heavy and light bronze or brass castings, for parts of machinery etc., are made in great perfection, there really does not exist, we believe, in Great Britain a single bronze-foundry devoted solely to the speciality of fine-art castings.

Nor are we likely soon to see such, for a great foundry of Bronzes, as objects of high art, demands the combination of two classes of industrial ability, only one of which we, as a nation, can command from amongst ourselves. We must obtain the respective manual skill of the moulder and founder, and, in addition, the hand and eye and genius of the modeler and the metal-chaser; and we may add, above all, that generally advanced and educated standard of taste amongst our people, more especially of the wealthier classes, to appreciate and reward their combined efforts. This combination, of distinct but closely allied and mutually helping talents and powers, can never be broken up and yet success await the issue.

It is for this reason that, while we have had Bramahs (the younger), Robinsons, and Cottams etc., spasmodically attempting the art, and indeed making very fair castings—merely viewed as such—and have had (to say nothing of divers "men in brass jackets") colossal lions, moulded by a painter and cast by a marble sculptor, we have never yet produced a first-rate group in bronze; nor ever established artistic bronze-casting as a fine-art industry amongst us. The Bramahs and Cottams etc., were mere moulders, brass-founders; the Marochettis, whatever they may have been as sculptors, were trading speculators in casting statuary; an art of the refinements and details of which they personally knew nothing, and for the execution of which, in their pompously styled *ateliers*, they were dependent upon the hireling skill of workmen, who well knew the practical ignorance of their employers.

Prussia and Austria—especially the former—have been a good deal more successfull; and almost wholly because they could command the poetry of art, and bring it into the foundry, which we cannot do. And perhaps there is no single modern monument of fine-art bronze-casting in Europe or in the world, at present, of nobler conception and execution than the grand equestrian statue of Frederick the Great, with its surrounding figures and colossal base, on the Linden at Berlin.

Russia, too, has had her long-descended line of first cousins to bronze-founding in the men who cast the gigantic bells of the Kremlin, and her huge old bronze guns; and their descendants have produced some very noble statue-castings, such as the Colossus of Peter the Great, and a good many very finely-cast statues of smaller size, such as the horses and horse-tamers presented to Ferdinand of Naples by the late Emperor of Russia, which are over the piers of entrance to the Palace garden at Naples.

But all these have been spasmodic efforts, sporadic results; in France alone has artistic bronze-casting taken firm root, not as an appanage of despotic extravagance, but as a noble and genuine branch of industry. It would almost seem as if this Roman art had descended to the French, as certainly the lineal successors in many respects of Rome, and the people over the face of whose country Rome spread more widely and choicely the education and the solid monuments of her civilization, than over any other area in Europe. This, however, would be but a fancy: the expansion and success of fine-art bronze manufacture in France, and, *par excellence*, in Paris, has really been due to the art-loving genius and impressionable imagination of her people, to their art-education, long continued and well understood by those who have conducted it in successive decades; and to the patience and *habileté* of her workmen, supported and empowered by the genuine knowledge and metallurgic science of those who lead them.

On the whole, brass and bronze-founding is much more of a speciality in France, in all its departments, than it has (hitherto at least) ever been in England. We do not make any reference now to Government foundries, such as the bronze gun-foundries of France or of England.
